Surgical site infection (SSI), the presence of necrotic tissue, the presence of a foreign body, an immunocompromised state, ischemia, and poor surgical closure technique all can contribute to failed wound healing and possibly wound dehiscence. Wounds are classified by their native propensity for infection as clean, clean contaminated, contaminated, and dirty. Clean wounds are uninfected with little or no inflammation, and dirty wounds are those with gross contamination such as fecal matter. Clean-contaminated and contaminated wounds lie somewhere in the middle of this spectrum.⁹⁹ Although a clean or clean-contaminated surgical wound may be purposely closed by primary intention, a contaminated or dirty wound is left open to close slowly by granulation and wound contraction (secondary intention). Alternatively, a contaminated wound may be left open for several days prior to being closed (delayed primary closure) to prevent infection. The healing processes are similar in these various approaches to wound

management. Successful healing of a closed surgical wound yields mechanical integrity by virtue of high tensile strength. Successful healing in an open wound may be measured by epithelialization with the promise of satisfactory mechanical integrity (scarring) over time. Understanding these inter-related processes facilitates logical wound care and helps to avoid diversions from normal wound healing.

EPITHELIALIZATION AND WOUND CARE

Development of an epithelial barrier begins within hours of injury. In partial-thickness wounds, the source of epithelial repopulation is remaining dermal structures, sweat glands, and hair follicles. Epithelial cells from the basal layers of the wound migrate across the underlying extracellular matrix, re-forming the characteristic basal to apical differentiation, until migration halts in the center of the wound because of contact inhibition. Wound coverage can be complete 24 to 48 hours after a clean surgical incision is closed by primary intention. At this time, no further wound protection is necessary, and skin cleansing with water is permitted. Bacteria, necrotic tissue, wound exudates, inflammatory cells, inflammatory mediators, and desiccation all retard re-epithelialization. Deeper or open wounds also show delayed epithelialization. Open wounds first must fill in with proliferating fibroblasts, capillaries, and a loose extracellular matrix made of collagen and proteoglycans (granulation tissue) before epithelialization can occur. Such tissue is of poor mechanical integrity.

The ability of epithelialization to occur from the margin of the wounds over the granulation tissue depends on the presence of adequate angiogenesis, absence of bacterial burden, the provision of a moist environment, and the removal of excess necrosis and proteinaceous exudates (which contain proteases and inflammatory mediators and support bacterial growth). With optimal circumstances, the maximal rate of epithelialization from the margins occurs at 1 to 2 mm/day. As the epithelial cells mature and stratification progresses, keratinization occurs.

Without moist, occlusive dressings over superficial wounds, eschar forms, delaying epithelialization. Only with clot proteolysis can the wound be resurfaced successfully. If the wound is kept moist with an occlusive dressing,¹⁰⁰ however, and accumulated exudates and necrotic tissue are removed frequently, epithelialization can occur. Small amounts of wound exudates and necrotic tissue can be removed with frequent, moist dressing changes and water irrigation; larger amounts may require surgical débridement. The optimal wound dressing provides a moist environment, has absorptive reserve to trap wound exudates, possesses bacteriostatic properties, and does not adhere to the wound. Large, open wounds may be dressed with moist gauze at the surface and reinforced with dry gauze packing (wet-to-dry dressing). Absorptive capacity is limited, however, and frequent dressing changes are required. Dressings made of hydrocolloids, materials that incorporate high-capacity absorptive materials into a self-adhering occlusive backing, are useful for open wounds of moderate size and allow for less frequent dressing changes. More recently, the vacuum-assisted closure has gained popularity for the management of large open wounds. Vacuum-assisted closure therapy is the combination of moderate suction applied

above an absorptive surface, such as a towel or sponge, which is covered by an occlusive plastic drape. The application provides for increased blood flow, the promotion of angiogenesis, a reduction of wound surface area in certain types of wounds, and induction of cell proliferation. However, at this time, vacuum-assisted closure therapy has not been shown to reduce edema, improve bacterial clearance, or increase the speed of healing in chronic wounds.^{101,102}

OPTIMIZING WOUND HEALING

The first rule of wound evaluation is “take off the dressing and look at the wound.” Wounds should be evaluated at least daily or with each dressing change in the case of vacuum-assisted closure therapy for progression of healing and development of infection. Normally healing surgical incisions should be dry with a minimal dry eschar at the point of closure. The edges should have at most a 3- to 4-mm border of erythema and induration when fresh, which should resolve over about 1 week.

ANTIBIOTICS

The routine use of systemic antibiotics to aid wound healing, in the absence of actual SSI, should be avoided. Wound surfaces are typically colonized by bacteria, and this colonization is not detrimental to wound healing. An increased bacterial load, more than the typical colonization, may impede wound healing, however. Distinguishing between common colonization and an increased bacterial burden requires microbiologic confirmation. Simple swab cultures lack specificity, and quantitative tissue cultures revealing greater than 10^5 organisms per gram are necessary to identify true bacterial infection. Topical antibiotics are commonly applied to wound surfaces, but the benefits of topical antibiotics are not well documented.^{72,103} The incorporation of silver into dressing materials adds bacteriostatic properties and may be useful to limit bacterial overgrowth in the wound.

SURGICAL SITE INFECTIONS

Infections of surgical incisions are referred to as *surgical site infections* (SSIs).^{104,105} SSIs are *superficial* incisional SSIs when limited to skin and subcutaneous tissues above the fascia or *deep* incisional SSIs if extending below. Intracavitary SSIs are referred to as organ-space SSIs. The surgical site becomes inoculated either inward from the skin or outward from the structures beneath the incision. Most SSIs are caused by the gram-positive cocci found on the skin, such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Enterococcus* species. The type of operation also can influence the causative organisms of the SSI such that enteric aerobic gram-negative rods (*Escherichia*, *Enterobacter*) and anaerobic organisms (*Bacteroides*) are more likely after intestinal or head and neck surgery.⁷⁶

Although it was once believed that mechanical bowel preparation would decrease postoperative infectious complication rates, this practice has not survived prospective validation.¹⁰⁶ The use of skin preparations, in addition to the use of narrow-spectrum “prophylactic” systemic antibiotics, has reduced the incidence of SSIs by decreasing bacterial numbers. However, the administration of prophylactic antibiotics beyond 24 hours, even in the presence

of colonic perforation or shock, does not contribute further to reducing the rate of SSIs.¹⁰⁷ In addition, prolonged use of prophylactic antibiotics may result in the emergence of multiple drug-resistant strains of organisms, *Clostridium difficile* colitis, nosocomial pneumonia, and catheter-related infections.¹⁰⁸ It is important to discontinue prophylactic antibiotics before the benefits of such therapy are overshadowed by the risks that their continuation brings with them.

A daily wound evaluation is necessary to identify early signs of wound infections. Nonpurulent drainage is not likely to be infected. Clear drainage from the wound may simply be escaping subcutaneous edema fluid or may signify seroma formation. However, wounds with an enlarging border of erythema and induration, without fluctuance or drainage, particularly when painful to palpation, suggest cellulitis or infection of deeper structures. Fluctuance and drainage may be from an abscess beneath the wound. Drainage that is turbid or frankly purulent should suggest true SSI. SSIs require opening of the incision for irrigation and drainage. Antibiotics may not be needed for uncomplicated SSIs, which respond to this intervention and local care.⁷⁶

More complicated SSIs require systemic antibiotics directed at the likely pathogens. Culture of pus collected aseptically is useful to guide therapy, but simple swab cultures of the wound surface are of low specificity because of the presence of wound colonizers. Necrotizing SSIs can spread rapidly through soft tissues and involve the fascia (necrotizing fasciitis). Necrotizing soft tissue infections can have subtle findings at the skin surface (e.g., an advancing border of erythema), while forging a destructive path just below. Wounds that dehisce superficially or at the fascia should suggest aberration of normal wound healing. Dehiscence almost always requires surgical evaluation. When an abdominal wound has open skin, evaluation for status of the fascial closure is needed. The mechanical integrity can be evaluated by gently probing the closure with sterile cotton-tipped swabs. The edges of these wounds should show yellow fat or pink granulation. Dark gray, nonviable tissue should be obvious on inspection and should be debrided.

DRAINS

Few things in the postoperative patient are more puzzling and sometimes intimidating to the uninitiated than drains. Seemingly simple in construction and intuitive in purpose, the efficacy of these devices and their application is quite limited. A study of the history of drainage is a study in the evolution of medicine and surgery itself. The earliest description of drains shows their application for the removal of fluid from large cavities, such as the pleural space, abdomen, and bladder, and for the treatment of wounds.

Drains can be classified on many levels.¹⁰⁹ Drains with one end open to the atmosphere are known as “open” systems and constitute most early devices. Before the recognition of germ theory, it was not appreciated that open systems provided a free route for entrance of infectious agents into the body. Some open systems employed a filter at the open end to limit the ability of microorganisms to enter the system. “Closed” systems of drainage have no opening to the atmosphere directly; fluid collection terminates in a bag or canister.

Structurally, drains can be classified as “hollow” or “capillary.” Hollow drains take on many shapes, but all have one or multiple internal lumens and have fenestrations throughout a portion of their length, sometimes including their ends. Fenestrations must be large enough to allow fluid and debris to enter, but not so large as to allow significant portions of tissue, such as omentum or intestine, to enter. Such migration into the drain has been the cause of drain failure, tissue adhesion, and organ injury. Capillary-type drains leverage the physical interaction that occurs between liquids and the walls of thin tubes and fibers. Structurally, capillary-type devices are made from tufts of thin fibers, fabrics (e.g., gauze), or thin tubes. Drains should be soft and flexible, but not so much that the lumen collapses with suction. Irritating materials, such as latex rubber, should be avoided (except in cases in which development of a fibrous tract is desired, such as in T-tube biliary drainage). Siliconized materials (Silastic) and polyvinyl chloride are commonly used in contemporary drainage systems.

Drains can be classified as “passive” or “active.” Passive drains provide a route of low resistance to the body’s exterior and are driven by capillary action and pressure gradients. Capillary-type drains are classified as passive drains. Active drains use an external source of negative pressure to establish a pressure gradient. Active drainage of deep recesses is classified as sump drainage. Sump drains were ultimately modified so that an additional lumen running alongside the primary lumen supplied atmospheric gas into the drainage site to prevent the intestine and omentum from occluding the fenestra.¹¹⁰ Sump drains are used to drain the gastrointestinal tract and abscess cavities. Active drainage employing a closed system is used to obliterate potential spaces, particularly under skin/muscle flaps or other wounds.

Drains also are classified as therapeutic or prophylactic.¹¹¹ Therapeutic drainage is intended to remove necrotic debris, pus, or fistula drainage or to prevent premature closure of wounds. Prophylactic drainage is intended to prevent the accumulation of blood, pus, bile, pancreatic secretions, intestinal contents, and fluids. In the historical literature of medicine and surgery, it was noted that patients with ovariectomy developed accumulations of blood and fluid in the pelvis. It was believed that this fluid, in stagnation, would decompose and release toxins whose absorption resulted in fatal outcomes. In 1882, drains were used to “remove from cavities fluids liable to undergo putrefactive changes if retained and to cleanse such cavities by injection of disinfectants.”⁸⁰

The popularity of drainage in certain applications waxed and waned owing to its controversial effect on outcome, particularly mortality risk. When surgeons abandoned the use of abdominal drains during World War II, mortality rates decreased by 50% compared with those of World War I.¹¹² The use of prophylactic drains, particularly in abdominal surgery, was equally controversial. Capillary-based systems, which did more to prevent drainage of necrotic or purulent material than facilitate its removal, ultimately fell out of favor. Complications increased from the use of multiple or unnecessary drains and included ventral hernias, pain on removal, omental penetration of the drain’s fenestrations, intestinal obstruction, adhesions (occasionally pulling omentum or bowel into the abdominal wall), fecal fistulas,

and persistent sinus tracts. The pioneering surgeon Halsted believed that good surgical technique and obliteration of dead space obviated the need for drainage in nonseptic instances. He believed that drains “invariably produce some necrosis of tissue with which it comes in contact and enfeebles the power of resistance of tissues toward organisms. But given necrotic tissue plus infections, drains become almost indispensable.”⁸⁰ Prophylactic drainage ultimately gave way to therapeutic drainage. In the 1920s, indications for drains included the “presence of free purulent material in considerable quantity . . . and the presence of an abscess sac.”⁸⁰

Currently, the indications for drainage include the following:

- Removal of cerebrospinal fluid (CSF) from the brain’s ventricles or spinal cord for the purpose of reducing pressure in a closed space and improving perfusion pressure
- Removal of blood or fluid from the subdural space to prevent compression or shift of intracranial contents
- Closure of certain soft tissue wounds to minimize dead space and remove excess fluid and debris; often seen in neck surgery, breast surgery, and certain reconstructive procedures
- Drainage of the pleural space in the event of pneumothorax, hemothorax, or large pleural effusions
- Drainage of the pericardium to treat large pericardial effusions
- Drainage of abscess cavities; drains can be placed directly in the operating room or percutaneously with the guidance of imaging technologies
- Drainage of existing fistulas to create a controlled route of elimination; includes drainage of bile or pancreatic secretions, succus, or stool
- Surveillance drainage over the sites of complicated procedures involving the stomach, duodenum, pancreas, and rerouting anastomoses

Placement of surveillance drains is controversial because of the risk of creating a fistula by the drains themselves. However, in the event of a catastrophic breach in enteral integrity, such as the highly morbid duodenal stump “blow-out,” early identification and controlled drainage may be facilitated by placement of such a drain.

In general, the following questions must be answered for all drains:

1. What is the intended anatomic location of the drain?
2. How can location be confirmed?
3. What is the expected quantity and quality of the drain’s output?
4. Is the drain functioning normally?
5. When should a drain be removed and according to what criteria?

Only by knowing the intended anatomic location of a given drain can a clinician determine the best way to confirm location and assess function. The visual location of a drain on physical examination does not ensure proper placement; a thoracostomy tube seen to penetrate the chest wall may not be in the pleural space, and a gastrostomy tube seen to penetrate the abdominal wall does not guarantee that the

tip lies in the stomach. Sometimes the location of a drain cannot be confirmed, such as drains left in the peritoneum. This, short of advanced imaging techniques, leaves only assessment of quantity and quality of drain output as a guide to the drain’s proper location and function. For these reasons, it is useful to know certain characteristics of specific drains.

The most common drains seen after neurosurgical procedures are the subdural drain and the ventriculostomy. The former drain is usually a Silastic drain left in the subdural space to drain blood or fluid after craniotomy. There is no way to confirm its location. These drains typically drain about 20 to 30 mL of serosanguineous fluid per hour until tapering off to minimal drainage after about 6 hours. Frankly bloody drainage, particularly when in higher volumes or persisting longer than a few hours, suggests active bleeding that requires correction of coagulopathy or neurosurgical intervention. The ventriculostomy tube, also made of Silastic, has its tip located in a lateral ventricle. The proper tip location can be confirmed by seeing a pulsatile waveform when the catheter has continuous pressure monitoring and by seeing CSF output. About 450 mL of CSF is produced a day; the volume of CSF drained depends on the height of the drainage system’s external port relative to the height of the catheter’s tip in the ventricle and the ability of the arachnoid granulations to reabsorb CSF. The fluid may be clear or sanguineous depending on the intracranial surgery performed. CSF that changes from clear or serosanguineous to frankly bloody suggests a serious problem, particularly in subarachnoid hemorrhage. Declining or absent CSF drainage or loss of a pulsatile waveform suggests tube occlusion by clot or malposition and requires neurosurgical attention.

Thoracostomy tubes are placed to drain pleural effusions and treat pneumothorax. Thoracostomy tubes can be inadvertently placed subcutaneously. Proper location is confirmed by chest radiograph. The tube may be intentionally positioned in many orientations; however, the most proximal “sentinel” hole should always lie within the pleural space, and the tube should not be kinked. A properly functioning, correctly located thoracostomy tube should show a cycling of intrapleural pressure with respiration when the drainage system is on “water seal.” Absence of cycling may suggest tube occlusion or inappropriate location. Bubbling across the water seal suggests an air leak, but does not indicate the source of the leak. Persistence of the bubbles across the water seal when the thoracostomy tube is clamped close to the chest wall indicates a leak in the drainage system, not in the lung. Variable amounts of suction can be applied to the thoracostomy tube, particularly when draining an effusion or reinflating a lung after pneumothorax. Initial suction of -20 cm H_2O is appropriate in this clinical situation. Persistence of sanguineous drainage greater than 200 mL/hour for 2 to 3 hours after the correction of hypothermia and coagulopathy suggests surgical bleeding and requires attention. When fluid drainage has diminished to about 100 to 200 mL/day or air leaks have ceased, external suction can be removed, and the water seal alone can be used to prevent lung collapse. If effusions or pneumothorax do not return, as assessed on chest radiograph, the thoracostomy tube can be removed.

Nasogastric or orogastric tubes are used to decompress the stomach or provide a route for nutrition. Double-lumen sump tubes should never have the secondary port clamped; this secondary port prevents mucosal injury in the presence of suction. Inadvertent placement in the airways can be disastrous if enteral feedings are administered. Confirmation of gastric placement cannot be guaranteed by listening over the epigastrium during insufflation. Correct placement on radiograph is recognized by identifying the distal tip well below the diaphragm. Salivary and gastric output can be 0.75 to 1.5 L/day each. Continuous gastric suction can result in significant volume and chloride loss, leading to metabolic alkalosis. Gastric suction should be maintained until resolution of enteral obstructions or ileus. When the daily volume of gastric aspirate is less than 200 to 300 mL, gastric suction can be discontinued as long as nausea, vomiting, or abdominal distention does not result.

The color of gastric aspirate should be clear or yellow-green. Large volumes of bilious aspirate suggest the distal port of the drain is positioned beyond the pylorus. "Coffee grounds" or frank blood in the aspirate suggests bleeding in the stomach or duodenum. The stomach also can be accessed by placement of a surgical or percutaneous endoscopically assisted gastrostomy. These tubes infrequently migrate out of the stomach to lie in the peritoneum. Should acute abdominal pain or absence of typical gastric drainage occur in a patient with a recently placed gastrostomy, a radiographic contrast study of the gastrostomy should be done to exclude tube migration.

The liver produces 500 to 1500 mL of bile daily. Drainage of the common bile duct via a T-tube is used after complicated biliary surgery, often for obstruction. T-tubes are used less than in the past now that transhepatic catheter drainage and common bile duct stents/sphincterotomy are more commonplace. The drainage tube itself causes a modest inflammatory reaction resulting in the formation of a fibrous tract. The drainage system is closed, without suction, and terminates in a collection bag. Significant reduction or cessation of biliary output may suggest either obstruction or malposition of the T-tube or resolution of the obstruction.

With the exception of drains placed in abscess cavities and to control the direction of pancreatic and enteral fistula output, drains left in the abdominal cavity are seen less frequently than in the past. Drains left in the peritoneum should have relatively little output. Confirmation of their location is usually unnecessary. A change in the quality or quantity of drainage is important to note. New bile, succus entericus, or stool in a drain suggests a breach in the integrity of some part of the viscera and requires investigation or surgical attention.

Drains placed in subcutaneous spaces or areas of reconstruction are placed to gentle suction to obliterate potential spaces and remove excessive fluid and blood collection. Confirmation of absolute location is generally unnecessary. The quality of the fluid should be serous to serosanguineous in volumes less than 100 mL hourly for the first 3 to 6 hours postoperatively before tapering off. Frankly bloody drainage in higher volumes or of longer durations suggests surgical bleeding in the absence of coagulopathy.

KEY POINTS

- Optimally, the location of a patient in the ICU is determined by matching the patient's needs with a location's resources and expertise.
- The postoperative evaluation should include a thorough evaluation of the patient's medical and surgical history and a physical examination, which should encompass all parts of the patient that can be accessed by sight and touch.
- "Adequate resuscitation" is a state, often temporary, that allows for good clinical perfusion and physiologic stability. The most fundamental concept is to ensure adequate DO_2 and meet the VO_2 needs of tissues and organelles.
- Resuscitation targets are reproducible, quantifiable values, such as pressures, outputs, metabolites, inflammatory mediators, or oxygen saturations, that represent therapeutic goals. Targeted resuscitation strategies optimize cardiovascular performance and concurrently measure markers of adequate global DO_2 and tissue use.
- Analgesics should be administered as the patient is resuscitated from anesthesia to facilitate comfort and avoid interference with medical care.
- Resuscitation should be complete, with hemostasis achieved, metabolic acidosis resolving, vasoactive support and gas exchange abnormalities minimized, anesthetic agents cleared, the ability to protect the airway present, and the patient awake and reasonably cooperative prior to initiating weaning from mechanical ventilation.
- Nutritional support is an important consideration in ICU patients due to the ongoing caloric demands of these complex patients. Early assessment of the available routes should be performed and the appropriate supplementation should be incorporated into the patient's daily care.
- Successful healing of a closed surgical wound yields mechanical integrity by virtue of high tensile strength. Successful healing in an open wound may be measured by epithelialization with the promise of satisfactory mechanical integrity (scarring) over time.
- The ability of epithelialization to occur from the margin of the wounds over the granulation tissue depends on the presence of adequate angiogenesis, the absence of bacterial burden, the provision of a moist environment, and the removal of excess necrosis and proteinaceous exudates (which contain proteases and inflammatory mediators and harbor bacterial growth).
- The first rule of wound evaluation is "take off the dressing and look at the wound." Wounds should be

KEY POINTS (Continued)

evaluated at least daily for progression of healing and for development of infection.

- Only by knowing the intended anatomic location of a given drain can a clinician determine the best way to confirm location and assess its function.

Role of Ultrasonography in Postcardiotomy Tamponade

Rescue Applications of Echocardiography

MISCELLANEOUS CONSIDERATIONS

Intra-aortic Balloon Pump Weaning

Routine Order Sets

Intensive Care Unit Length of Stay

This chapter will give the reader information on how to manage routine and complex cardiac surgery patients in the immediate and early postoperative period. The disproportionately small number of patients who undergo cardiac operations and have prolonged intensive care unit (ICU) stays often develop complications not unique to them but common to most ICU patients who have delayed recoveries or do not survive after a long ICU course. These ICU complications are covered elsewhere in this text. This chapter is divided by organ system into five broad areas (neurologic, cardiac, pulmonary, renal, transthoracic echocardiography) specific to these patients in this setting and includes a discussion of some miscellaneous topics.

NEUROLOGIC CARE

Despite improvements in cardiac surgery techniques and perioperative critical care, postcardiotomy neurologic complications remain a major cause of morbidity and death following cardiac surgery. A spectrum of neurologic complications is seen in the postoperative period. Complications can be classified as generalized (global deficit) or focal. Generalized deficits can be manifested as delayed awakening from general anesthesia, coma, or new onset of seizure. Focal deficits may be transient or permanent. Except in their most severe form, neurologic complications cannot be completely assessed until the patient returns

to consciousness and is weaned from the ventilator. Focal abnormalities are usually evaluated by a computed tomography (CT) scan. A CT for nonfocal, cognitive dysfunction rarely yields new information that is helpful for patient management, and imaging studies most often show old, chronic changes such as atrophy or lacunar infarcts. The patient must be stable enough to withstand transport to the CT (if the institution does not have a portable scanner), which is usually not the case in the early postoperative period.

The risk factors for neurologic injury after cardiac surgery have been well elucidated, but effective risk modification to reliably prevent neurologic complications has been elusive. In certain operations, measures to reduce risk have been implemented and have become incorporated in perioperative management.^{1,2} For example, patients with descending thoracic aortic operations are at significant intraoperative risk for spinal cord ischemia, as well as delayed injury (days postoperatively). These patients usually have a spinal drain placed preoperatively to reduce the risk of spinal cord injury. Spinal cord perfusion pressure (SCPP) is the difference between mean arterial pressure (MAP) and cerebrospinal fluid pressure (CSFP) ($SCPP = MAP - CSFP$); thus, lowering of CSFP will increase SCPP and potentially improve neurologic function as long as an adequate MAP is maintained.³

Neurologic complications are still considered one of the major risks associated with coronary artery grafting. The

advanced age of bypass patients, high incidence of associated carotid occlusive disease, and increased aortic athero-embolic burden place older coronary artery bypass graft (CABG) patients at increased risk of central neurologic complications in the postoperative period.⁴

Other strategies for preoperative and intraoperative risk modification are becoming routine. They include selective use of preoperative carotid imaging, routine use of intraoperative transesophageal echocardiography (TEE) and epiaortic echocardiography, descending aortic cannulation with TEE guidance, aortic-no-touch technique, high-flow/high-pressure cardiopulmonary bypass (CPB), retrograde cerebral perfusion during circulatory arrest, carbon dioxide insufflation, intraoperative cerebral oxygen saturation monitoring, echocardiography de-airing, and maintenance of baseline perioperative blood pressure.^{5,6} Early neurologic complications vary in clinical presentation from focal to global neurologic deficit such as seizures, ischemic encephalopathy, and coma. Several authors have classified these complications as type I (focal injury, stupor, and coma) and type II (seizures, neurocognitive dysfunction, and delirium).⁷ This classification does not emphasize pathophysiologic mechanisms that could better inform preventive measures.^{5,7} Regardless of the classification system used, overlap often exists.

In comparison to the other complications, focal neurologic deficits from stroke carry a mortality rate of up to 20% in the first postoperative month and prolong ICU and hospital lengths of stay.⁸⁻¹⁰ In a mixed cardiac surgery patient population, the incidence of stroke varied among those patients having CABG, combined CABG and heart valve surgery, and ascending aorta repair.¹¹⁻¹³ The incidence of stroke depends on the surgical procedure (isolated CABG, 1.4-3.8%; combined CABG and valve, 7.4%; isolated valve, 4.8-8.8%; multiple valve, 9.7%; and aorta, 8.7%).¹²

Unfortunately, most of the known baseline patient variables associated with perioperative stroke are not modifiable. Despite the identification of many intraoperative variables that cause intraoperative stroke (macroembolism of debris, air embolism, hypoperfusion, hypoxemia, coagulation status), risk remains significant and continues in the early postoperative period. Although there was early enthusiasm for off-pump CABG as an operative technique to reduce stroke, in the most recent multicenter clinical trial the 30-day incidence of stroke was not significantly decreased compared with on-pump CABG.¹⁴

The majority of strokes are ischemic (62%); fewer are due to hypoperfusion (9%) or hemorrhage (<1%).¹² Hemorrhagic strokes are rare after cardiac surgery and the clinical presentation is notable for delayed awakening and coma despite discontinuing sedation or progressive clinical deterioration as intracranial pressure (ICP) increases. Hemorrhagic transformation is recognized in 20% of ischemic strokes.¹⁰ Embolic strokes tend to present with acute hemiparesis and represent a compromise of specific cerebral artery area. Thrombotic or ischemic strokes are related to diminished blood flow with the most vulnerable areas being those between major cerebral artery perfusion territories (watershed areas).

Cardiac transplantation has a higher associated occurrence of neurologic complications than CABG.^{15,16} Symptom onset for focal motor deficits in these patients usually

occur after the second postoperative day, especially in patients receiving mechanical circulatory support or experiencing major postsurgical complications such as tamponade, severe cardiac dysfunction, prolonged CPB, or postoperative hepatic failure.

Predictive models may enable implementation of earlier interventions.¹⁴ More than half of strokes are identified within the first day after CABG.¹⁰ Because of associated morbidity and death, an objective neurologic evaluation by minimizing sedation in the first 2 postoperative hours is desirable. Weaning sedation should be initiated only when the risk of doing so is minimal (i.e., a normothermic, non-acidemic, nonagitated patient with minimal chest tube output).

Once a new focal neurologic deficit, seizure, or delayed awakening is documented, a noncontrast brain CT scan should be obtained immediately. The most important tomographic findings include loss of insular ribbon, loss of gray-white interface, loss of sulci, acute hypodensity, mass effect, and dense mean cerebral artery sign. Owing to the relative insensitivity of CT scans for diagnosing ischemia, early CT scans may be normal, despite areas of brain infarction.¹⁷ Magnetic resonance imaging (MRI) may help identify these lesions.¹⁷ MRI usually cannot be obtained safely in the early postoperative period because of the need to move the patient off the unit to a usually remote location and because non-MRI compatible pericardial pacing wires are routinely placed in cardiac surgery patients. MRI will document a new lesion in 26% to 50% of cases, but there is often lack of correlation with the neurocognitive deficit.^{18,19} Brain CT scans are more sensitive in diagnosing large air embolism, which is often the cause of abnormal postoperative neurologic findings in these patients. In the patient with a focal deficit or persistent embolic events, transcranial Doppler, transthoracic echocardiography (TTE), or TEE can be used to help identify sources of recurrent cardiac or aortic embolization.

Stabilization of the patient who develops stroke after cardiac surgery is the most important initial intervention and includes continuation of cardiopulmonary support and tracheal intubation if the patient cannot protect the airway or has a Glasgow Coma Scale score less than 9. Secondary brain injury, which is additional brain injury due to the factors that initially caused an imbalance between oxygen supply and demand, should be prevented. The most important measures are prevention of hypoxemia, hypotension, hypercarbia, and hyperthermia.

From a ventilator standpoint, higher levels of positive end-expiratory pressure (PEEP) to maintain optimal oxygenation might be required. If the patient has documented intracranial hypertension and requires PEEP 10 cm H₂O or higher, ICP monitoring should be considered as high levels of PEEP and lung recruitment maneuvers may decrease cerebral perfusion. Increased PEEP may decrease cerebral perfusion pressure (CPP) by elevating ICP because CPP is the difference between MAP and ICP.

Although acute treatment of ischemic stroke is imperative, the traditional 3-hour time window for active stroke intervention and institution of thrombolytic therapy is often lost because the time of the last known normal is usually just before induction of anesthesia and duration of surgery usually exceeds 3 hours. Furthermore, intravenous

administration of tissue plasminogen activator (tPA) is contraindicated in the immediate postoperative period because of the associated postoperative bleeding risk.

Intra-arterial administration of tPA is an alternative for acute treatment of ischemic stroke within 6 hours of clinical presentation. The safety and efficacy of intra-arterial urokinase and tPA in selected patients who presented ischemic stroke within 12 days after cardiac surgery have been demonstrated.²⁰ The mean time from operation to stroke was 4.3 days. Thrombolytic therapy was commenced within 3.6 hours. No operative intervention for bleeding was necessary and 38% of the patients had neurologic improvement. Mechanical clot retrieval is another acute stroke therapy in the first 8 hours since neurologic deficit. Patients who will likely benefit from this therapy include those with significant neurologic deficit and large vessel occlusion with core ischemia approximately less than 30% of the middle cerebral artery territory.

Anticoagulation therapy has not proved beneficial in the cardiac surgery patient with ischemic stroke. However, it should be considered in cases of basilar stenosis, internal carotid dissection, and suspected cardiac embolism and specifically with concurrent atrial fibrillation and stroke. In this circumstance, the risk of ongoing embolism to cerebral circulation may be considered higher than active bleeding after cardiac surgery. A hematology consult is recommended in cases of suspected hypercoagulable state as the cause of this disorder demands a more comprehensive workup and potentially may require lifelong anticoagulation therapy. Antiplatelet therapy should be initiated in all cardiac surgery patients with acute stroke, especially if thrombolytic therapy is contraindicated. Aspirin is usually prescribed. The dose ranges between 160 mg and 1300 mg per day. Combined antiplatelet therapy with clopidogrel is not recommended because of the significant risk of bleeding.

In cases of suspected perioperative air embolism (i.e., opening of heart chambers for valve repair or replacement), the patient should remain in the supine position to avoid further embolic phenomena. If tolerable, the patient should be maintained in Trendelenburg position and mechanical ventilator support with FIO_2 of 1.0 should be instituted. Measures to control intracranial hypertension (more common in intracranial hemorrhage) should be individualized after reassessment of brain CT imaging. Hyperventilation, as well as diuresis with mannitol or furosemide is recommended in the patient with intracranial hypertension.

In the cardiac surgery patient, coma is defined as prolonged unconsciousness after discontinuation of anesthetics, sedatives, and opioids and inability to show response to motor/verbal commands. A recent retrospective investigation found an incidence of delayed awakening in approximately 0.5% of all cardiac surgery patients.²¹ However, the period of time in the immediate postoperative phase can be challenging as the necessity of adequate neurologic examination must be weighed against the patient's hemodynamic stability. If a specific diagnosis is not found, and there is concomitant severe heart failure, it portends a worse outcome.²¹ Moreover, up to 20% of patients with postcardiotomy stroke present with delayed awakening and coma-like symptoms.²¹

Evaluation with brain CT is mandatory in these cases and it should occur as soon as the coma state has been recognized and reversible metabolic causes have been treated. The identified risk factors for delayed awakening after cardiac surgery in the aforementioned investigation included urgent cardiac surgery, elevated serum creatinine (Cr), and lower postoperative hemoglobin level.²¹ Most of these patients had normal brain CT scan imaging and ultimately recovered consciousness after being comatose during the first 24 hours.²¹ Although some investigators have proposed a role for altered renal excretion of sedatives in patients with postoperative renal failure or decreased oxygen delivery to the brain with anemia, the specific underlying mechanisms in these cases remain unclear.

Postoperative seizure is an independent predictor of permanent neurologic deficit and increased mortality risk.^{22,23} A recent study showed seizures were a strong predictor of permanent neurologic deficit and increased mortality risk. It is important to remember that any neurologic injury can present initially as a seizure. The independent risk factors for postoperative seizures included deep hypothermic circulatory arrest, aortic calcification or atheroma, and critical preoperative state. Other specific risk factors for early seizures include perioperative administration of the antifibrinolytic tranexamic acid administration and preexisting renal insufficiency.

Tranexamic acid has proconvulsant properties and it is reasonable to hold the infusion of this agent in the early postoperative period if the patient presents with seizures. The most common proposed mechanism of seizures after cardiac surgery is focal or global ischemia from hypoperfusion (air or atheroembolism) or metabolic disorders. Early brain CT scan is essential because it may detect potential reversible causes of neurologic injury such as cerebral edema, intracranial bleeding, or emboli in a major cerebral artery.¹⁰

Delirium is considered a subtle category of brain injury in the postcardiotomy patient. The intensivist should include perioperative stroke in the differential diagnosis of perioperative psychomotor agitation or delirium in the ICU. A common missed diagnosis is drug and alcohol withdrawal in patients with acute delirium in the ICU.

CARDIOVASCULAR CARE

HEMODYNAMIC CHANGES

Patients undergoing CABG or valvular surgery often exhibit hemodynamic instability in the postoperative period. The pathologic remodeling secondary to preexisting cardiovascular disease, the inflammatory cascade initiated during CPB, and the changes in loading conditions and oxygen demand after surgical repair predispose these patients to hemodynamic perturbations following cardiac surgery. In the postoperative period, these patients frequently require pharmacologic support for maintenance of normotension and adequate cardiac output. In some cases of severe, refractory, cardiogenic shock, institution of mechanical ventricular support is required.

MEAN ARTERIAL PRESSURE

MAP is one of the most commonly measured and manipulated hemodynamic variables in the perioperative period. Although MAPs are routinely maintained in the 70 to 80 mm Hg range, target blood pressure may be altered based upon comorbid disease and the intraoperative course of events. Hypertensive patients with neurologic or renal disease may have altered autoregulatory curves, which require higher blood pressures for adequate end-organ function. Conversely, in patients with friable cardiac tissue, tenuous surgical repairs, or uncorrected aneurysmal disease lower MAPs may be desirable. Ideally, intraoperative manipulation of the blood pressure while observing the echocardiogram and changes in central venous (CVP) and pulmonary artery pressures (PAPs) will allow the practitioner to define optimal blood pressure.

HYPERTENSION

Cardiac surgical patients presenting in the postoperative period with hypertension should be evaluated for routine causes of acute postoperative hypertension and treated accordingly. Pain, residual neuromuscular blockade, hypoxemia, hypercarbia, hypothermia, or bladder distention may provoke hypertension. If these precipitants are ruled out, pharmacologic lowering of blood pressure with an infusion of a vasodilator, sodium nitroprusside, or nitroglycerin can be initiated. The rapid titratability and short duration of action of these medications is desirable as hemodynamic lability is commonplace. Alternatively, short-acting or ultra-short-acting dihydropyridine calcium channel blockers (e.g., nicardipine or clevidipine) have been used as they exert maximal effect in the peripheral arterial system with minimal impact on cardiac function.²⁴ While MAP is lowered, serial measurements of cardiac output and urine output should be recorded to assess the patient's tolerance of a lower blood pressure.

HYPOTENSION

With a reported incidence of 9% to 44%, hypotension is more common than hypertension following cardiac surgery.²⁵ Studies of off-pump CABG surgery compared to on-pump CABG surgery have demonstrated a significant increase in the incidence of hypotension in those patients exposed to CPB.²⁶ Some clinicians also associate the relatively common hypotensive response to more critically ill patients with prolonged medical management prior to surgery. Additionally, widespread use of angiotensin-converting enzyme inhibitors has been implicated as a potential contributor.²⁷ Regardless of the predisposing factors, postoperative hypotension demands prompt investigation and treatment.

From a physiologic standpoint, $MAP = \text{central venous pressure (CVP, mm Hg)} + \text{cardiac output (CO, L/minute)} \times \text{systemic vascular resistance (SVR, dyn}\cdot\text{s}\cdot\text{cm}^{-5})$. A decrease in any of these parameters will reduce MAP. It is useful to consider the common causes of postoperative hypotension relative to these hemodynamic variables. Low CVP corresponds with hypovolemia. Decreased CO can occur as a consequence of cardiac insufficiency/cardiogenic shock or

new-onset myocardial ischemia. Vasoplegia following CPB leads to a depressed SVR. Routine causes of hypotension in the acute postoperative period include hypovolemia, cardiac insufficiency/cardiogenic shock, vasoplegia following CPB, new-onset myocardial ischemia, and tamponade. Crucial to postoperative management is understanding the patient's intraoperative hemodynamics and immediate postbypass cardiac function.

The most readily correctable cause of hypotension is hypovolemia. Commonly boluses of crystalloid (500 mL to 1 L of 0.9% normal saline or lactated Ringer's solution) are administered and the patient's hemodynamic responses (MAP, CVP, PAP, and cardiac index [CI]) are evaluated. Colloid solutions can be used, but some concern exists when administering hetastarch solutions because of its effects on the coagulation cascade and potential contribution to a bleeding diathesis.²⁸

A low preoperative ejection fraction (<35%), advanced age (>70 years old), and prolonged CPB times (>120 minutes) correlate with an increased risk of decreased cardiac output in the postbypass period.²⁹ Postoperatively, a depressed CI often manifests early, during separation from CPB in the operating room. The pattern observed on hemodynamic monitoring is a depressed CI (<2.2 L/minute/m²), hypotension, normal or elevated SVR, and elevated filling pressures. Echocardiography demonstrates global ventricular hypokinesia. Patients will frequently require exogenous pharmacologic support to maintain a CI of greater than 2.2 L/minute/m². Epinephrine, dopamine, dobutamine, or milrinone may be initiated for inotropic support.³⁰ It is not uncommon for cardiac insufficiency to persist for several days following CPB.

Even after successful coronary revascularization, the astute practitioner must be vigilant for postoperative myocardial ischemia. During weaning from CPB, air may become entrained within the heart that is not effectively evacuated by the atrioventricular (AV) bypass vents. Some of this air may enter the coronaries and lead to cardiac arrest or ischemia. In addition, during chest closure, bypass grafts may become kinked, obstructing flow. During aortic or valvular surgery, graft material or sutures may inadvertently obstruct coronary ostia or may occlude native coronary flow. Although multiple patient monitors—electrocardiogram (ECG), pulmonary artery catheter, and echocardiography—can identify ischemia, studies have demonstrated new-onset wall motion abnormalities on echocardiography as the most sensitive and earliest indicator of malperfusion.^{31,32} If ischemia is present, surgical revascularization or percutaneous coronary revascularization may be necessary for reestablishing flow.

For approximately 5% to 15% of patients, exposure to CPB will lead to a prolonged vasodilatory state or vasoplegia.³³ The classical pattern is normal biventricular function, normovolemia, and decreased SVR. In these patients, infusing additional volume will not increase MAP and will frequently decrease systemic pressure secondary to activation of the atrial stretch receptors. In patients who are adequately volume resuscitated, the most effective treatment is infusion of a vasopressor, commonly norepinephrine, phenylephrine, or vasopressin.¹⁰ Patients requiring progressively increasing doses of vasopressors should be continually assessed for hypovolemia or anemia, as these problems

might happen concurrently in the vasoplegic patient. Experimental evidence suggests that these patients may suffer from a relative vasopressin deficiency. As such, exogenous vasopressin added to one of the other aforementioned vasopressors has been used successfully to maintain an adequate MAP.³⁴

TAMPONADE

Acute tamponade is a surgical emergency that demands immediate treatment. In the early postoperative period following cardiac surgery, tamponade may occur as a consequence of uncorrected coagulopathy or from chest tube obstruction. Classic signs of tamponade on physical examination include hypotension, pulsus paradoxus, diminished peripheral pulses, and oliguria. Invasive hemodynamic monitoring may demonstrate equalization of CVP, pulmonary artery (PA) diastolic, and PA systolic pressures as the pericardium fills and pericardial pressure exceeds intracardiac pressures. Echocardiographic signs include right atrial systolic collapse and right ventricular diastolic collapse.³⁵

Unfortunately, although prompt recognition and treatment are crucial, many patients with tamponade fail to demonstrate classic physical examination findings. Depending upon the rate of accumulation, hypotension may be sudden and severe or may occur gradually over a period of hours. If decompensation is sudden and severe, emergent bedside reexploration is warranted. Otherwise, the patient may be taken to the operating room for emergent chest evacuation.

ARRHYTHMIAS

Postoperative arrhythmias are the most common complication after cardiac surgery with an overall reported incidence of 5% to 63%.³⁶ The most frequent arrhythmia is atrial fibrillation, which occurs in up to 40% of patients following bypass graft surgery and 60% of patients following combined CABG valve surgery.³⁶ Inflammation of the myocardium and mechanical disruption of the cardiac conduction system during surgery predispose cardiac surgical patients to bradyarrhythmias and heart block during the postoperative period. Accordingly, placement of temporary epicardial pacing wires in the ventricles and atria is routine.³⁷ Atrial wires will allow for AV synchrony during contraction, but removal of these wires from the more fragile atrial tissue may place the patient at an increased risk of atrial damage and tamponade.

Given the association of supraventricular arrhythmias with increased morbidity and length of stay, considerable research effort has focused on prevention and treatment.³⁸ In the postoperative period, 60% of arrhythmias manifest within the first 3 postoperative days.³⁸ For the patient with new-onset atrial fibrillation or flutter, the first step is to decide whether any hemodynamic instability is present. In the unstable patient, preparations should be made for immediate cardioversion according to Advanced Cardiac Life Support (ACLS) guidelines. In the hemodynamically stable patient, examination of the serum metabolic panel should be done for evidence of hypokalemia or hypomagnesemia with repletion of potassium or magnesium as necessary. If atrial fibrillation persists, the clinician must decide

whether rate or rhythm control is preferred. Although rate control will limit tachycardia and myocardial oxygen consumption, it will not provide the benefit of atrial contraction and requires long-term anticoagulation.

If rate control is deemed appropriate for the patient, the most common agents used include beta blockers (e.g., atenolol or metoprolol), calcium channel blockers (e.g., diltiazem or verapamil), and digoxin.³⁸ Care should be avoided when administering beta blockers to patients with severe chronic obstructive pulmonary disease (COPD) or reduced ejection fraction.

In patients with atrial fibrillation or flutter for less than 48 hours or with an echocardiogram devoid of intracardiac thrombus, rhythm control can be attempted. Prior to initiation of antiarrhythmic therapy, a 12-lead ECG should be examined for evidence of QT interval prolongation. The most common medications used for rhythm control include amiodarone, sotalol, procainamide, and ibutilide. In patients with decreased ejection fraction, amiodarone is the agent of choice. ECG monitoring should be performed during initiation and maintenance of rhythm control agents because any of these medications may provoke malignant arrhythmias. If medications fail to restore sinus rhythm and atrial fibrillation or flutter is less than 48 hours in duration, synchronized cardioversion with a biphasic defibrillator can be performed.

BLEEDING

If left untreated, hemorrhage and uncorrected coagulopathy can lead to devastating complications in the cardiac surgery patient. Excess bleeding occurs in 20% of cardiac surgical patients with approximately 5% requiring surgical reexploration.^{39,40} Many factors contribute to this increased risk of hemorrhage. Preoperatively, patients are routinely on antiplatelet therapy and anticoagulant medications. Intraoperative exposure to CPB initiates contact activation of platelets with resultant thrombocytopenia and thrombocytopenia. In addition, the extracorporeal circuit exacerbates inflammation and amplifies fibrinolysis.⁴¹

Thromboelastography (TEG) and point-of-care (POC) testing are useful to guide blood product administration as the rapid rate of bleeding in the cardiac surgery patient outpaces the results obtained with standard laboratory testing.^{42,43} In contrast to management of anemia in medical patients, transfusion of blood products in cardiac surgical patients is often determined by immediate clinical findings (e.g., intraoperative surgical field oozing, increased postoperative chest tube output, or hypotension). Increased rate of bleeding, greater than 500 mL over 2 hours, usually correlates with a source of bleeding that is amenable to surgical repair. Many institutions have established criteria upon which the surgical team will reexplore the patient for evacuation—chest tube output of greater than 500 mL within the first 2 postoperative hours requires surgical exploration. Initial evaluation of the bleeding cardiac surgery patient should focus on any abnormal physiologic parameters that may contribute to ongoing coagulopathy—severe acidemia, alkalemia, or hypothermia will impair hemostasis and should be corrected.

With the advent of cell-salvage technologies and increasing recognition of the adverse effects of red blood cell

transfusion, there has been a decrease in the amount of blood given in the perioperative period.^{44,45} Decisions regarding administration of red blood cells are based on patient-specific factors, including comorbid conditions and the adequacy of revascularization. Current American Society of Anesthesiology Practice Guidelines recommends transfusion of red blood cells when hemoglobin levels are less than 6 g/dL. Above this level, evidence of organ malperfusion and ischemia should be demonstrated prior to red blood cell transfusion.⁴⁶

Given the deleterious effects of CPB circuitry on platelet quantity and function, hemorrhage that does not appear to have an overt surgical source often requires platelet transfusion. In a cardiac surgical patient with microvascular bleeding and normal physiologic parameters (normothermia, normal acid-base balance, etc.), platelet transfusion should be strongly considered. A platelet count greater than $100 \times 10^9/L$ usually excludes thrombocytopenia as a contributing factor in the hemorrhagic cardiac surgical patient.⁴⁶

Although intraoperative cell salvage has reduced the need for packed red blood cell transfusion, the washing of the blood during this process eliminates essential clotting factors.⁴⁷ Per American Society of Anesthesiology Guidelines, elevation of the prothrombin time (PT) greater than 1.5 times normal or elevation of the activated partial thromboplastin time (aPTT) greater than 2 times normal is an indication for fresh frozen plasma (FFP) transfusion. Although no specific algorithms exist for cardiac surgery, FFP administration is reasonable in the patient with normal platelet count and evidence of persistent bleeding.⁴⁶

Pharmacologic options for reducing bleeding in the perioperative period include antifibrinolytic agents, desmopressin, and activated factor VII.⁴⁸⁻⁵⁰ For maximal efficacy, antifibrinolytics should be started in the operating room prior to incision. Studies of desmopressin have demonstrated a reduction in blood loss, but no overall decrease in transfusion requirements. The newest hemostatic agent used for excess hemorrhage in the cardiac surgical arena is activated factor VII. Although approved for hemostatic control in hemophilia A or B patients, it has been successfully used off-label in cardiac surgery patients. Studies thus far have been encouraging, demonstrating decreased bleeding and transfusion requirements.^{50,51}

PULMONARY CARE

Fluid overload is a common cause of poor gas exchange in the early postoperative period and can be readily assessed by reviewing intraoperative fluid balance and postoperative indicators of volume status. A positive intraoperative fluid balance greater than 4 L, and increased CVP and PA diastolic pressures are typical in fluid-overloaded patients. Pulmonary artery occlusion pressures do not have to be obtained or followed in this assessment. Unless early renal insufficiency has occurred, fluid-overloaded patients usually respond well to aggressive diuretic therapy with furosemide (intermittent dosing or a continuous infusion of up to 20 mg/hour).

Atelectasis is common in these patients and may not become clinically significant until after extubation when sedation and positive-pressure ventilation have been

discontinued, especially in patients who are fluid overloaded. Atelectasis may lead to inadequate gas exchange, require better pain management, and mask continuous positive airway pressure (CPAP) while more aggressive diuresis is carried out. Adequate pain management is required to allow the patient to breathe deeply and perform incentive spirometry. Positive expiratory pressure therapy, EzPAP Positive Airway Pressure System (Smiths Medical), or other modalities employed by respiratory therapists early and continued until the patient is fully mobilized are imperative. If not prevented or treated early, atelectasis may lead to reintubation and possibly to pneumonia. Most lung dysfunction in the initial postoperative period is due to atelectasis, which usually responds well to higher PEEP levels.

A right mainstem intubation may lead to left-sided atelectasis and can be corrected early by careful inspection of the first postoperative chest radiograph when endotracheal tube position and position of mediastinal and plural chest drains as well as proper expansion of both lungs are determined. Bronchial obstruction by a mucous plug with lobar collapse commonly occurs, especially in the right lower lobe. Effective treatment usually requires removal of the plug either by aggressive pulmonary toileting or by bronchoscopy with bronchoalveolar lavage followed by a period of higher PEEP if the patient is still on ventilator support to reexpand the lung. Unless the plug is removed and the airway cleared, reexpansion is unlikely. Rarely, collapse of the right upper lobe may be seen in the case of superior lobe bronchus take-off directly from the trachea and occlusion there by the endotracheal tube. Review of the postoperative chest radiograph will usually lead to early diagnosis and treatment.

Simple pneumothorax may be seen on the first postoperative chest radiograph and may be corrected by increasing chest tube suction up to -20 cm H₂O in an optimally placed chest tube, or by placement of another chest tube usually in a more apical position. Postoperative pulmonary air leak from disruption of the visceral pleura in one or more areas may lead to tension pneumothorax if occult or unrecognized and chest tubes are removed prematurely.

Pleural effusions present after chest tubes have been removed are common but usually do not require removal by thoracentesis or chest tube thoracostomy unless they cause respiratory symptoms (Fig. 36.1). Hemothorax not due to ongoing postoperative bleeding is typically from bleeding that was not adequately drained by pleural or mediastinal chest tubes and does not usually require specific treatment.

Patients with baseline abnormal pulmonary function will usually manifest it to a worse degree postoperatively. Some patients, however, with preoperative cardiogenic pulmonary dysfunction improve often promptly after surgery (e.g., mitral stenosis, acute mitral regurgitation, or severe aortic stenosis).

Unanticipated, severe pulmonary dysfunction may be due to acute lung injury and is usually associated with inflammation and hemodilution related to CPB, particularly after long operations. After CPB, the lungs are especially susceptible to cytokine-mediated systemic reperfusion-inflammation injury due to the high blood flow they receive, or they may be injured by their own ischemia-reperfusion when there is no ventilation or pulmonary

Figure 36.1 The examination of the pleura. Recognition of pleural effusion.

blood flow during CPB and oxygen delivery is by nonpulsatile bronchial flow only. Regardless of the mechanism, some pulmonary dysfunction is nearly universal.^{52,53} Manifestations include decreased $\text{PaO}_2/\text{FiO}_2$ ratio, decreased pulmonary compliance, large alveolar-arterial gradients, and bronchoconstriction.

The management of these patients is similar to that for patients with acute respiratory distress syndrome. This requires adequate sedation and frequently muscle relaxation to better ventilate the patient by improving both coordination with ventilator cycles and chest wall compliance. Postinjury lung protective strategies include low tidal volume (6 mL/kg) delivered by pressure control ventilation. A low tidal volume minimizes volutrauma and decreases minute ventilation, which results in hypercapnia that is acceptable as long as the pH remains greater than 7.25. A lower pH especially in postoperative cardiac surgery patients is not well tolerated because inotropes are less effective and arrhythmias more likely in the setting of severe acidemia. PEEP up to 20 cm of H_2O as hemodynamically tolerated may be required to wean FiO_2 levels below 60% to decrease the risk of free-radical-induced secondary lung injury. High PEEP may not be well tolerated in these patients due to impaired venous return and decreased cardiac output. Acute lung injury may occur as part of the systemic inflammatory response to CPB and does not typically progress to acute respiratory distress syndrome. With these lung-protective measures, more aggressive mechanical ventilation and muscle relaxation are not typically required and secondary lung injury is rare.

Postoperative diaphragm dysfunction may account for pulmonary problems in these patients. A paralyzed or palsied diaphragm may be suspected by finding an elevated hemidiaphragm on the first postoperative radiograph or after weaning from positive-pressure ventilation. Diaphragmatic dysfunction secondary to phrenic nerve injury (hypothermia, retractor stretch, or direct injury with mammary dissection) may prolong weaning or make weaning from ventilator support impossible.

Abdominal compartment syndrome from massive interstitial edema or retroperitoneal bleeding may occur after a long CPB time or intra-aortic balloon pump (IABP) insertion, respectively. In this case, the diaphragm is pushed into

the thoracic cavity because of increased intra-abdominal pressure and excursion becomes minimal. Peak inspiratory pressures are high and it is difficult and often impossible to ventilate the patient adequately. Laparotomy and temporary expanded abdominal closure may be required to enable normal ventilation.

An increasing number of cardiac surgery patients are being successfully extubated in the operating room. The majority of patients who are not weaned and extubated in the operating room as part of an accelerated recovery protocol are candidates for extubation within 2 to 4 hours after ICU admission. Early postoperative conditions that mitigate against the initiation of ventilator weaning on arrival to the ICU after surgery are listed in [Box 36.1](#).

A protocol-driven and respiratory therapist-managed reduction in initial postoperative intubation time has been achieved in many ICUs.⁵⁴ Some institutions use inclusion/exclusion criteria for selecting patients to be weaned under an accelerated recovery protocol.^{55,56} Others employ a protocol wherein all patients are initially included, and a patient is excluded only when the patient does not meet the parameters for advancement. A practice that has been successful is to preoperatively select patients for accelerated recovery and make a final extubation decision in the operating room at the end of the case with input from both surgeon and anesthesiologist.

Tracheostomy is considered in patients who are difficult to separate from ventilator support. Tracheostomy reduces total mechanical ventilation time, shortens ICU and hospital stays, decreases the occurrence of pneumonia, reduces in-hospital mortality rate, and improves hospital resource utilization. It usually increases patient comfort and tolerance of mechanical ventilation and facilitates nursing care. It can improve communication and oral hygiene and make mobilization easier. It decreases the number of self-extubations and extubation-reintubation cycles, and decreases the requirement for sedation. Tracheostomy may also reduce upper airway injury including vocal cord ulceration, decrease dead space ventilation and airway resistance, and optimize work of breathing, thus facilitating separation from ventilator support, allowing for earlier transfer out of the ICU.

Although tracheostomy has conventionally been considered in patients who are ventilator dependent 2 weeks

Box 36.1 Early Postoperative Conditions or Criteria That Mitigate Against Initiation of Ventilator Weaning on Arrival in the ICU After Cardiac Surgery*

Primary Adverse Criteria

- Hemodynamic instability due to:
 - Atrial or ventricular arrhythmias
 - Low cardiac index
 - Hypotension, unexplained or uncontrolled
 - High level of inotropic or pressor support
- Ventilatory dysfunction
 - Low PaO₂/FiO₂ ratio
 - Difficult airway/intubation
- Excessive postoperative bleeding (>200-300 mL/hr)
- Hypothermia
- Mechanical ventricular assist
- Open sternum

Secondary Adverse Criteria

- Intra-aortic balloon pump counterpulsation support
- Long-standing pulmonary hypertension
- Operation for:
 - Acute myocardial infarction
 - Acute ventricular septal defect
 - Acute mitral regurgitation (papillary muscle rupture)
 - Descending aortic aneurysm

*Notably few of these are absolute contraindications to ventilator weaning, but they warrant consideration in the aggregate (see text).

FiO₂, fraction of inspired oxygen; ICU, intensive care unit; PaO₂, partial pressure of oxygen in arterial blood.

after cardiac surgery, there is little evidence to support this approach. Tracheostomy timing can be based on the determination at the end of the first ICU week of a patient's likelihood of successful weaning over the second week. If at that time successful weaning is considered unlikely, tracheostomy should be considered. Earlier tracheostomy (before the tenth postoperative day) in patients who require prolonged mechanical ventilation after cardiac surgery is associated with lower morbidity and mortality rates as well as decreased ICU and total hospital lengths of stay, and is not associated with an increased occurrence of mediastinitis.⁵⁷

Venovenous extracorporeal membrane oxygenation and nitric oxide are two other modalities employed infrequently in selected patients with severe refractory respiratory failure after cardiac surgery. Nitric oxide has been used most effectively in patients with severe right ventricular dysfunction due to new-onset pulmonary hypertension to reduce right ventricular afterload. It is used under a protocol starting at 40 ppm and only continued if there is an immediate beneficial effect (reduction in pulmonary artery systolic pressure of 25% or greater). Weaning nitric oxide is usually first attempted within 24 hours of initiating it using PA pressure change as the weaning parameter and discontinued as soon as possible.

RENAL CARE

Despite significant research efforts and considerable focus on prevention and treatment, acute kidney injury (AKI) following cardiac surgery is associated with a significantly increased risk of morbidity and mortality. Although only 1% of patients will experience the most severe form of kidney injury and require some form of renal replacement therapy, this patient population has a 60% in-hospital mortality rate.⁵⁸ Risk stratification has identified several preoperative and postoperative risk factors for postoperative AKI—these include female gender, left ventricular ejection fraction (LVEF) less than 35%, exposure to angiographic contrast dye, duration of CPB, and low MAP during CPB.⁵⁹

Causes of AKI are frequently divided into three distinct etiologic categories—prerenal, intrarenal, and postrenal. Although these aid in diagnostic evaluation, overlap may exist with multiple pathologic processes occurring in the same patient. Postrenal oliguria implies mechanical obstruction of the urologic system from the collecting ducts through the ureters. Diagnosis can be confirmed by Foley irrigation, renal and ureteral ultrasound, or computed tomographic scan of the abdomen and pelvis.

Prerenal causes occur when intravascular volume and cardiac output are insufficient to adequately perfuse the kidneys. In this state of ineffective circulating volume, the natural response of the kidneys is retention of blood volume and excretion of a small quantity of concentrated urine. If intravascular depletion or a depressed cardiac output persists, compensatory mechanisms may become overwhelmed. Thereafter, renal malperfusion becomes pathologic with the onset of acute tubular necrosis (ATN) and intrinsic renal injury.

Intrinsic renal failure refers to the state of direct damage to the kidney by ischemia or nephrotoxin exposure. The most common cause of intrarenal renal failure is ATN. This can result from prolonged periods of ischemia or exposure to nephrotoxic antibiotics, or contrast agents. Less commonly, certain medications (e.g., nafcillin or furosemide) can cause an inflammatory condition known as acute interstitial nephritis.

Initial evaluation of the patient with AKI should focus on the patient's preoperative risk factors, intraoperative course of events, exposure to nephrotoxic agents, and current hemodynamic and intravascular volume status. Laboratory parameters to assist in diagnosis of AKI include urine electrolytes, sodium (Na), Cr, blood urea nitrogen (BUN), and microscopic analysis of urine sediment. The fractional excretion of sodium (FeNa) or fractional excretion of BUN (FeBUN) is often used to distinguish prerenal causes of renal failure from intrarenal causes.

In the fluid-overloaded oliguric patient diuretics can be given to assess the patient's responsiveness and to remove excess volume. Although conversion from oliguric to non-oliguric renal failure through diuretics does not improve overall prognosis, it can improve oxygenation and hemodynamics.⁶⁰ If the patient is diuretic nonresponsive or has worsening electrolyte or acid-base imbalance, fluid overload with impairment of oxygenation or worsening heart failure, or has severe uremia, initiation of dialytic support should be considered. Several different dialysis modalities exist. In

brief, continuous therapies offer more stable hemodynamics but do not clear as much solute or fluid per unit of time as intermittent dialysis.⁶¹

APPLICATIONS OF ECHOCARDIOGRAPHY AFTER CARDIAC SURGERY

The use of ultrasonography in the perioperative period has increased significantly over the past decade. In contrast to TEE usually performed by cardiologists and cardiothoracic anesthesiologists in the operating room, focused TTE is well suited for the postoperative period especially for unexplained hypotension and assessment of response to therapeutic interventions. Postoperative use of TTE can provide rapid and accurate diagnostic information in patients developing potentially life-threatening conditions. Although the image quality obtained in mechanically ventilated patients is usually better with TEE, TTE usually provides adequate views in postcardiotomy patients; and it is noninvasive, fast, performed at the bedside, reproducible, and focused on major cardiac and pleural space abnormalities.^{62,63}

The use of TTE in periresuscitation (life support) care has two goals: (1) to assess the heart function, and (2) to identify treatable conditions. The focused echocardiographic evaluation in life support (FEEL) examination is briefly performed during cardiopulmonary resuscitation (CPR) with the primary objective of identifying potentially reversible causes of cardiopulmonary deterioration. The

identification and appropriate management by TTE in the perioperative period of severe left ventricular dysfunction, pulmonary embolism, hypovolemia, or cardiac tamponade may be lifesaving.^{64,65}

The recommended echocardiographic window to perform the FEEL examination is the subcostal view (Fig. 36.2). The FEEL examination may distinguish “true” pulseless electrical activity (PEA) from pseudo-PEA.⁶⁶ A recent publication demonstrated that in 35% of patients with an ECG diagnosis of asystole, 58% of those with PEA, coordinated cardiac motion was detected (pseudo-PEA) and associated with increased survival. Echocardiographic findings altered management in 78% of cases.⁶⁴

In addition, FEEL protocol can facilitate the early detection of return of spontaneous circulation. One of the most common questions in the critically ill is the fluid responsiveness. Barbier and associates described the inferior vena cava (IVC) distensibility index in mechanically ventilated patients.⁶⁷ This index is based on change in size of IVC with respiration as it decreases with size with inspiration and increases with expiration:

Distensibility index =

$$\frac{\text{IVC max (end expiration)} - \text{IVC min (end inspiration)}}{\text{IVC min (end expiration)}}$$

In this equation distensibility index is expressed as a percentage. A distensibility index greater than 18% predicts fluid responsiveness.

THE FATE EXAMINATION

The focused assessed transthoracic echocardiography (FATE) examination is a qualitative POC ultrasonography, which is ideal within the ICU. The FATE examination should include qualitative assessment of left and right ventricular function and intravascular volume status as minimum required information (Fig. 36.3). It supplements the critical care evaluation in the perioperative setting.^{68,69} However, focused echocardiography does not replace a comprehensive echocardiogram performed per cardiology specialist whenever quantitative analysis or specific diagnoses such as endocarditis or valvular dysfunction are needed. Moreover, the correct application of this tool in postcardiotomy patients depends on the appropriate utilization of ultrasonography findings in the clinical context.⁷⁰

The main goal of the FATE examination is to better characterize the state of shock/hypotension, volume status, and pleural disease:

- Hypovolemia (measurement of IVC diameter and distensibility index)
- Myocardial dysfunction (qualitative evaluation of the right and left ventricles, measurement of cardiac output and pulmonary pressures) including patients with acute respiratory failure
- Pericardial effusion/tamponade (evaluation of tamponade physiology)
- Pulmonary embolism (changes in acute right ventricular dysfunction)
- Pulmonary edema (lines B, “comet tail” artifacts)
- Pneumothorax (the sliding sign)

The appropriate process of applying FATE examination includes (a) acquisition of images, (b) recognition of normal anatomy of the heart, (c) fundamental knowledge of the more relevant diseases, and more importantly (d) applying findings to the clinical context.

Figure 36.4 The focused assessed transthoracic echocardiography (FATE) protocol—transthoracic echocardiography views. 1, subcostal view; 2, apical view; 3, parasternal view; 4, pleural examination.

ACQUISITION OF IMAGES

Bedside ultrasonography and acquisition of cardiac images are not exclusive of the comprehensive transthoracic examination. Moreover, the FATE examination must be considered an extension of the physical examination. Thus, before obtaining images with echocardiography it is important to keep in mind the position of the heart within the chest and the direction of the ultrasound beam (Fig. 36.4). In addition, thoracic ultrasonography offers better sensitivity and specificity than plain chest radiography. The evaluation of the pleurae mandate the knowledge of anatomic structures above and below both diaphragms. The acquisition of images can be very challenging in the postcardiotomy patient. Most of the time at least one view can be obtained and the goal of exclusion of important disease is achieved. Up to 40% of patients in the ICU have limited acquisition of echocardiography views. Although the TEE is an invasive technique, the unparalleled quality of ultrasonography examination is well known (Tables 36.1 and 36.2).

ROLE OF ULTRASONOGRAPHY IN POSTCARDIOTOMY TAMPONADE

Postcardiotomy surgery tamponade (PCST) is perhaps the most important diagnosis in the patient recovering from cardiac surgery. Its early recognition and intervention have a direct impact in patients' outcome. The process of diagnosing PCST begins with the identification of clinical signs and confirmation of the diagnosis with appropriate tools subsequently. A high index of suspicion should be maintained throughout the early postoperative cardiovascular ICU (CVICU) hours. Usually a progressive decrease of cardiac output after increased chest tube drainage and increased filling pressures occurs with PCST.⁷¹

Clinical signs such as Beck's triad (hypotension, distended neck veins, and diminished heart sounds) and pulsus paradoxus are neither sensitive nor specific of PCST.⁷² Patients with other disorders such as constrictive

Table 36.1 The FATE Protocol: Technique

View	Location of Transducer	Probe Orientation Marker	Depth	Helpful Tips
Subcostal	2-3 cm below xiphoid process or RUQ if chest tubes are in place	~3 o'clock	15-25 cm	Hold the transducer from the top; apply angulations between 10 and 40 degrees
Subcostal–inferior vena cava	From the previous view, rotate transducer 90 degrees counterclockwise	~12 o'clock	16-24 cm	Supine position Keep right atrium to IVC junction on the screen Need to see the IVC merging into right atrium
Apical	Find the point of maximal impulse if feasible; otherwise, from anterior axillar line to nipple	~3 o'clock	14-18 cm	Ensure good contact with the rib (gentle pressure)
Parasternal–long axis	Third to fourth intercostal space	~11 o'clock	12-20 cm (up to 24 cm with pleural or pericardial effusion)	Ideally, left lateral decubitus position
Parasternal–short axis	Rotate 90 degrees clockwise from the parasternal–long-axis view, so ~2 o'clock	~2 o'clock	12-16 cm	<i>Aortic valve level:</i> Tilt transducer face slightly upward toward the patient's right shoulder <i>Mitral valve level:</i> Transducer is perpendicular to chest wall <i>Papillary muscle level:</i> Transducer faces slightly downward toward the patient's left flank

FATE, focused assessed transthoracic echocardiography; IVC, inferior vena cava; RUQ, right upper quadrant.

Table 36.2 Assessment of Structures with FATE Protocol

Assessment Focus	View(s)	Classification
Left ventricular (LV) function (qualitative)—“eyeballing”: thickness of the myocardium	Parasternal–long-/short-axis view Apical view, subcostal view	Normal function Mild to moderate LV dysfunction Severe LV dysfunction Hyperdynamic
Right ventricular function	Parasternal–long-/short-axis view Apical view, subcostal view	
Pericardial space	Parasternal–long-/short-axis view Apical view, subcostal view	Pericardial effusion Tamponade physiology
Pleural effusion and pericardial effusion	Parasternal–long-axis view	
Inferior vena cava (IVC)	Subcostal view of the IVC	Diameter measurement: 2-3 cm from right atrium Normal diameter: 2.1 cm Respiratory phase variations, ideally on spontaneously breathing patients

FATE, focused assessed transthoracic echocardiography.

pericarditis, severe COPD, morbid obesity, and right ventricular infarction might present with pulsus paradoxus. In contrast, this sign can be absent in patients with atrial septal defect, regional tamponade, pulmonary hypertension, COPD with cor pulmonale, aortic insufficiency, and even positive-pressure mechanical ventilation.⁷²

The various clinical presentations of PCST impose limitations to the FATE examination, especially posterior

compartmented effusion. In addition, clotted and loculated blood is echo-dense, somewhat more challenging to diagnose, and could be mistaken for the myocardium itself. As a rapid screening tool it can very helpful if collapse of the right ventricle is noticed in the long-axis parasternal view or collapse of the right atrium/right ventricle, or left ventricle in the apical or subcostal views (Figs. 36.5 to 36.7). In addition, documentation of abnormally increased

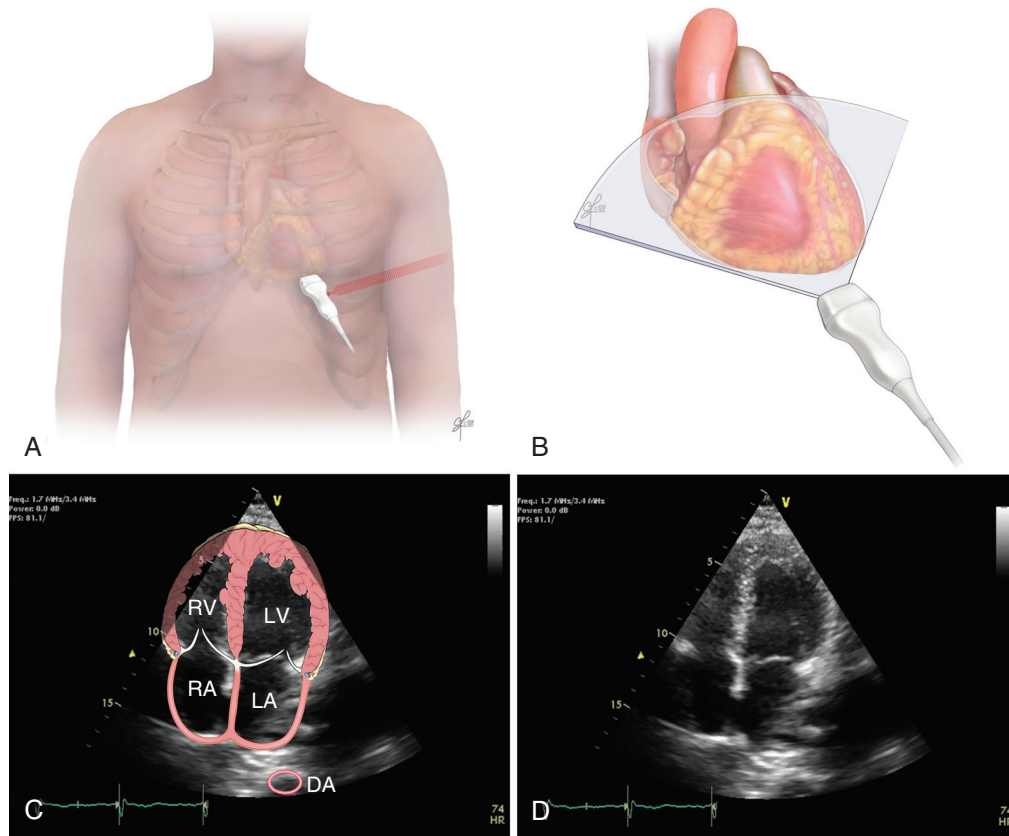

Figure 36.5 Apical view. **A**, Orientation of the probe in the apex. **B**, Direction of the ultrasound beam. **C** and **D**, Identification of cardiac chambers and heart valves.

Figure 36.6 Parasternal—long axis view. **A**, Orientation of the probe in the apex. **B**, Direction of the ultrasound beam. **C** and **D**, Identification of cardiac chambers and heart valves.

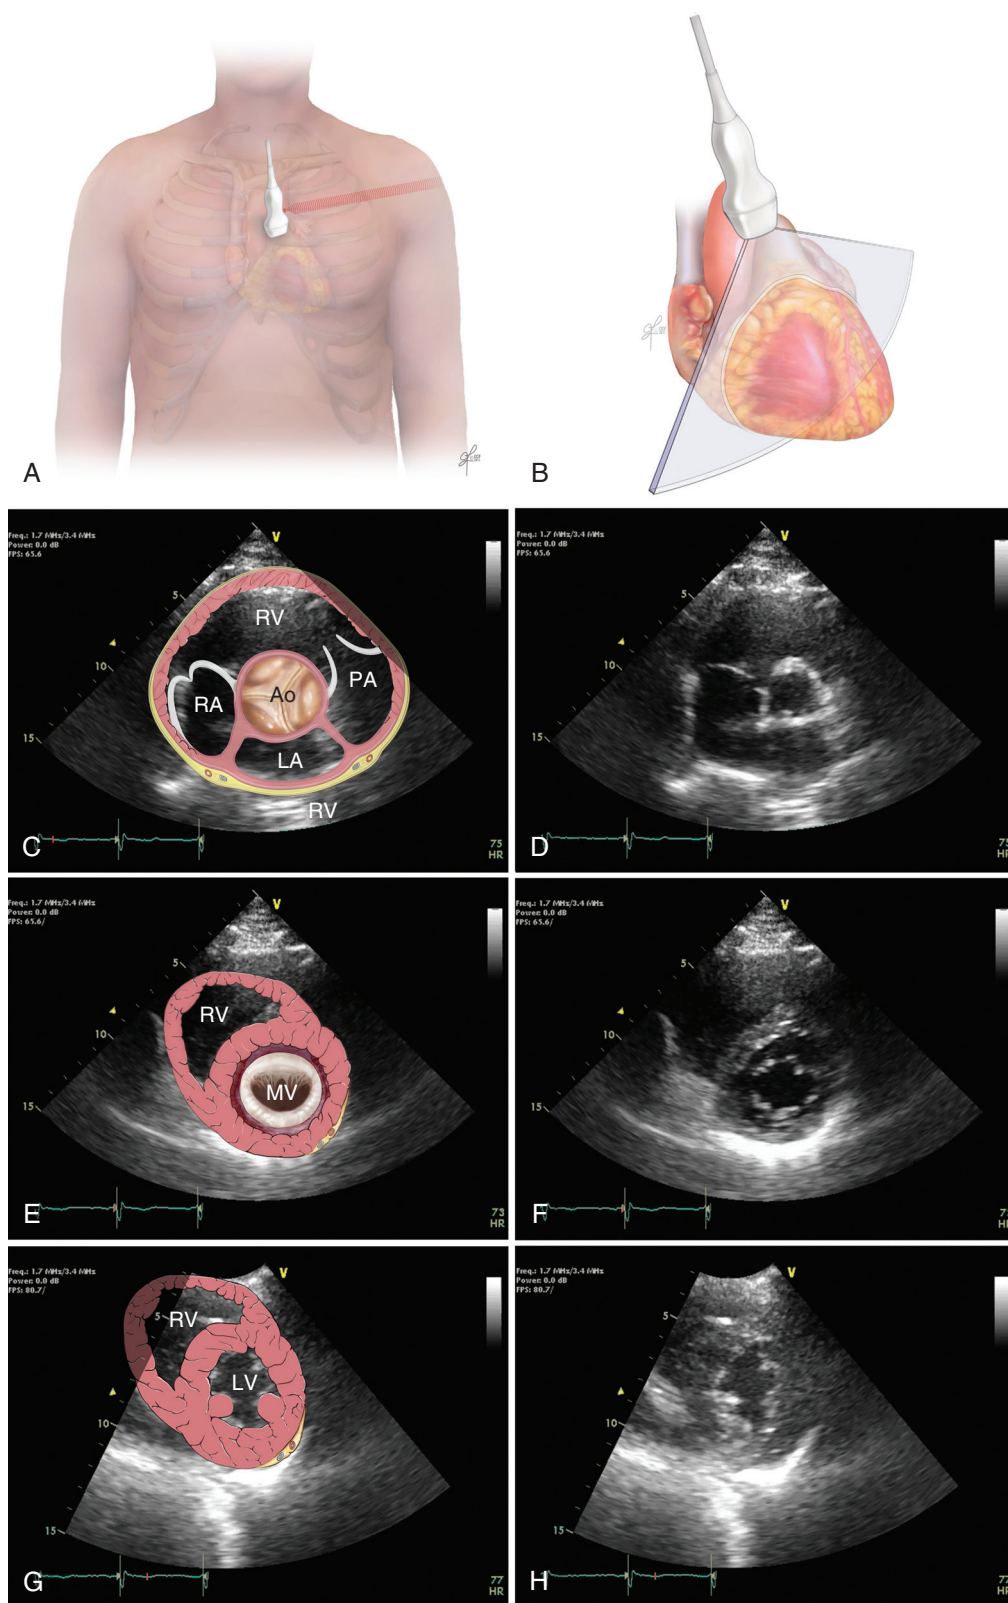

Figure 36.7 Parasternal—short axis view. **A**, Orientation of the probe in the left parasternal spaces. **B**, Direction of the ultrasound beam. **C** to **H**, Identification of cardiac chambers and heart valves.

Table 36.3 Echocardiographic Findings in Cardiac Tamponade

Typical	Atypical
Right atrium compression in early diastole*	Selective compression of the atria
Dilated inferior vena cava without respirophasic variability	Selective compression of right atrium
Echo-free space around the heart (circumferential pericardial effusion)	Bilateral atrial compression
Right ventricular diastolic collapse in the late diastole	Selective compression of right ventricle
Respirophasic variation of transmitral and transtricuspid flows	Selective compression of left ventricle
“Swinging heart” in the pericardial effusion	

*Right atrial collapse has higher sensitivity (68% vs. 60%) than right ventricular collapse but lower specificity (66% vs. 90%) in clinical tamponade. With hypovolemia this sign of tamponade might precede hemodynamic alterations.

diameter of the IVC (>2.5 cm) without variability with respiratory phases may help to distinguish from hemorrhagic shock in the setting of severe hypotension in the postoperative period.⁷³

Transesophageal echocardiography is the definitive test whenever FATE examination has no conclusive findings to support PCST despite high suspicion of atypical presentation. The performance of echocardiographic evaluations should not delay an emergency surgical reexploration in the setting of postoperative shock.

The presence of acute bleeding into the pericardial space makes it appear as echolucent space. The presence of blood in the pericardium can be graded as small (0.5 cm), moderate (0.5-2 cm), or large (>2 cm). Right atrial systolic collapse that has duration greater than 30% of the entire systole is the most sensitive and specific sign of PCST. The best views to recognize this finding are subcostal or apical view on TTE and midesophageal four-chamber view by TEE. Doppler ultrasound can reveal a 35% increase respirophasic variation of the tricuspid/mitral E-wave velocity during spontaneous inspiration and a decrease of 25% in the mitral or left ventricle outflow track flow. Another important and helpful finding is the paradoxical movement of the interventricular septum (shift of the septum to the left ventricle in diastole and toward the right ventricle in systole) during spontaneous expiration and normalization in controlled ventilation (Table 36.3). Absence of right atrial collapse in cardiac tamponade is seen in severe pulmonary hypertension, RV dysfunction, COPD with cor pulmonale, and regional posterior tamponade.

RESCUE APPLICATIONS OF ECHOCARDIOGRAPHY

- The use of focused echocardiography in periresuscitation following cardiac surgery intends to identify the four treatable causes of cardiac arrest (severe ventricular

dysfunction, pulmonary embolism, hypovolemia, and cardiac tamponade).

- The most useful echocardiography view in the setting of advanced cardiac life support is the subcostal. It can be performed after 5 cycles of CPR maneuvers.
- The identification of true PEA arrest has important prognostic implications as this subgroup of patients has worse prognosis in comparison to patients with pseudo-PEA (detection of coordinated cardiac motion).
- Post-cardiac surgery tamponade has various clinical presentations and may impose limitations to focused echocardiography, especially in those cases of posterior compartmented effusion.

MISCELLANEOUS CONSIDERATIONS

INTRA-AORTIC BALLOON PUMP WEANING

As noted elsewhere in this chapter, most patients with an IABP on arrival in the post-cardiac surgery unit have had the device percutaneously placed preoperatively in the catheterization laboratory. Appropriate management requires knowing the indication for its placement. In patients with unstable angina or left critical anatomy (usually a left main vessel obstruction, with or without proximal right coronary artery obstruction), the balloon often can be weaned as soon as the bleeding risks associated with removal are considered back to baseline. This may occur before extubation while the patient is still sedated. These are patients whose indication for IABP insertion has been corrected by the operation, and who do not require significant inotropic support, so the device is withdrawn in the early postoperative hours.

Less common and more challenging are the patients who had an IABP inserted for hemodynamic instability or cardiogenic shock preoperatively. In these patients, weaning from mechanical support may occur only after pharmacologic support (inotropes and vasopressors) has been weaned to a level that would allow them to be reinstituted or increased to support the patient after IABP removal. These are patients in whom a trial of ventilator weaning on IABP may be appropriate because the balloon unloads the afterload increases seen by a poor ventricle during awakening and ventilator weaning. In such patients, the IABP may be removed after extubation, but often ventilatory failure predominates, and the balloon weaning end points (minimal or no pharmacologic support) are reached well before extubation is an option. In these patients, mechanical support is weaned (decreasing the balloon augmentation ratio from 1:1 to 1:2 to 1:3, or by decreasing the balloon inflation volume). A normal response is to see the native (unloaded) systolic pressure increase as the MAP remains steady over 30 to 60 minutes. If these criteria are met, the balloon usually can be safely removed.

Patients who have an IABP placed intraoperatively may have had “prophylactic” mechanical support initiated, and, if on minimal pressor and inotrope support, with an anatomically corrective procedure, the device may be removed before extubation, as noted earlier. IABPs placed after CPB as an adjunct to weaning (see earlier) are frequently needed for days before successful weaning.

ROUTINE ORDER SETS

The post–cardiac surgery setting routinely makes good use of preprinted orders that, ideally, reflect a system-wide patient care pathway for the “typical” patient. It is important to review and revise these orders regularly to ensure that they remain appropriate in light of changes in accepted treatment principles and the institution’s patient population. The review and revision of these order sets should include a review of patient care pathways or protocols. Protocol modifications should be part of a process involving surgeons, anesthesiologists, intensivists, nurses, respiratory therapists, pharmacists, infectious disease specialists, and nephrologists.

INTENSIVE CARE UNIT LENGTH OF STAY

Initial intubation time is associated with ICU length of stay. Most cardiac surgery patients can be extubated early and transferred out of the ICU within 24 hours. Rapid patient turnover is achieved in ICUs that use care pathways based on patient parameters and not the length of stay.⁴⁹ Patient-based parameters for a diuresis protocol would be based on a patient’s weight relative to the preoperative weight, the BUN/Cr, and the CI/preload, not on time (“postoperative day 1”). When time-based parameters are used, they should be based on hours rather than days. Pacing wires might be removed routinely after any 12-hour period with no need for pacing or antidysrhythmic therapy, rather than “on postoperative day 2.” Timing of chest tube removal may be based on volume and character of the drainage, rather than on an experientially derived time or postoperative day.

KEY POINTS

- Despite decreased overall mortality risk in coronary artery grafting, postoperative neurologic complications remain the major cause of morbidity and death. Among these complications, stroke portends the worse outcome.
- The most consistent pathophysiologic mechanism of stroke is embolism (>60%), followed by hypoperfusion and hemorrhage.
- Clinical presentation of postcardiotomy neurologic complications include altered consciousness and coma, focal neurologic deficit, and seizures.
- Brain CT scan is indicated at any time postcardiotomy patients present unexplained delayed awakening, new focal neurologic deficit, or seizure.
- Although brain MRI is not usually feasible in the early postoperative period following cardiac surgery, it provides better characterization of the cerebral ischemic lesions and it has a definite prognostic value.
- The most important initial interventions of patients suffering from postcardiotomy stroke include tracheal intubation (if the patient has a GCS score <9), mechanical ventilatory support, and aggressive treatment of hypoxemia, hypotension, hypercarbia, and hyperthermia.

KEY POINTS (Continued)

- Thrombolytic therapy is a feasible therapy in selected patients who present postcardiotomy stroke.
- Perioperative hemodynamic perturbations are common in cardiac surgical patients and depend on the patient’s preoperative state, the nature of the surgical procedure, and the degree of intraoperative stunning.
- Optimal postoperative blood pressure should be determined in the context of the patient’s comorbid conditions and the nature of the surgical procedure.
- Postoperative hypotension may be secondary to hypovolemia, cardiac insufficiency, vasoplegia, myocardial ischemia, or tamponade.
- Myocardial stunning and vasoplegia usually require exogenous pharmacologic support and improve over hours to days.
- Acute tamponade requires immediate recognition and treatment; unfortunately, classic physical examination signs may not manifest.
- The most common arrhythmia following cardiac surgery is atrial fibrillation, and clinicians must decide whether rate or rhythm control is preferable for their patients.
- Bleeding following cardiac surgery is relatively common and often requires transfusion of packed red blood cells, platelets, and FFP.
- Fluid overload is a common cause of poor gas exchange in the early postoperative period and can be readily assessed by reviewing intraoperative fluid balance and postoperative indicators of volume status.
- Atelectasis is common in these patients and may not become clinically significant until after extubation when sedation and positive-pressure ventilation have been discontinued, especially in patients who are fluid overloaded.
- Pleural effusions present after chest tubes have been removed are common but usually do not require removal by thoracentesis or chest tube thoracostomy unless they cause respiratory symptoms.
- Patients with baseline abnormal pulmonary function will usually manifest it to a worse degree postoperatively.
- Unanticipated, severe pulmonary dysfunction may be due to acute lung injury and is usually associated with inflammation and hemodilution related to CPB, particularly after long operations.
- Postoperative diaphragm dysfunction may account for pulmonary problems in these patients. A paralyzed or palsied diaphragm may be suspected by finding an elevated hemidiaphragm on the first postoperative radiograph or after weaning from positive-pressure ventilation.
- A protocol-driven and respiratory therapist–managed reduction in initial postoperative intubation time has been achieved in many ICUs.

KEY POINTS (Continued)

- Earlier tracheostomy (before the tenth postoperative day) in patients who require prolonged mechanical ventilation after cardiac surgery is associated with lower morbidity and mortality rates as well as decreased ICU and total hospital lengths of stay, and is not associated with an increased occurrence of mediastinitis.
- Although AKI occurs in only 1% of cardiac surgery patients, it is associated with a 60% in-hospital mortality rate.
- Initial evaluation of the patient with AKI includes identification of patient-specific risk factors, estimation of intravascular volume status, and reduction of ongoing injury.
- Classification of AKI as prerenal, intrarenal, or postrenal has significant therapeutic and prognostic implications.
- Although diuretics may aid in removing excess volume, converting a patient from an oliguric to a nonoliguric state does not improve prognosis.
- Patients unresponsive to diuretic therapy who experience severe acid-base derangements, electrolyte abnormalities, or fluid overload impairing oxygenation, may require renal replacement therapy.

SUMMARY

ACUTE RESPIRATORY FAILURE—TYPES 1 AND 2

Acute respiratory failure is defined as the inability of the respiratory system to meet the oxygenation, ventilation, or metabolic requirements of the patient.¹ Although the main function of the lungs appears to be related to gas exchange (i.e., oxygenation and ventilation), it should be remembered that the lung is a metabolically active organ as well.^{1,2} Respiratory failure has been divided into two main types. Type 1 is hypoxemic respiratory failure, and type 2 is hypercapnic failure with or without hypoxemic respiratory failure.² More simply stated, type 1 respiratory failure is oxygenation failure and type 2 is ventilatory failure. Operationally, type 1 respiratory failure is defined by a partial pressure of oxygen in arterial blood (P_{aO_2}) less than 60 mm Hg and type 2 respiratory failure is defined by a partial pressure of carbon dioxide in arterial blood (P_{aCO_2}) greater than 50 mm Hg. The respiratory failure can be acute or chronic in nature, related to the onset and duration of the failure.^{2,3} Some patients may present with an acute deterioration or worsening of their chronic respiratory dysfunction termed *acute-on-chronic respiratory failure*.⁴

Acute respiratory failure is commonly encountered in the intensive care unit (ICU) setting and may be the primary reason for the admission or a complication of the patient's medical condition(s) or treatment. Respiratory failure may be the result of a variety of causes, some of which may not directly involve the lungs or the respiratory muscles.² Like a chain composed of individual links representing the brain, peripheral nervous system, upper airway, lower airway, respiratory muscles, cardiovascular system, and lungs (Fig. 37.1),²

respiratory failure may result when any of the links become sufficiently dysfunctional or weak. Like a chain, the body is only as strong as its weakest link, and respiratory failure may result when a component of the chain becomes sufficiently compromised. Common causes of hypoxemic and hypercapnic respiratory failure are listed in Box 37.1. This chapter reviews the basic mechanisms and clinical manifestations of type 1 and 2 respiratory failure and concludes with a more in-depth discussion of acute respiratory distress syndrome (ARDS), which includes clinical disorders in the type 1 category (ventilator management will be addressed in more depth in other chapters).

HYPOXEMIC RESPIRATORY FAILURE

BASIC MECHANISMS

Hypoxemic respiratory failure refers to the inability of the respiratory system to maintain satisfactory levels of oxygen in the arterial blood.³ The five basic mechanisms of hypoxemia are listed in Box 37.2. Ventilation-perfusion abnormality is the most common.^{2,3} Multiple mechanisms may be instrumental in the development of respiratory failure. Most of the abnormalities will improve with the administration of supplemental oxygen, except for a shunt abnormality in which the P_{aO_2} continues to be low despite the administration of high levels of supplemental oxygen. The shunt may be either intracardiac (such as a right-to-left shunt through a patent foramen ovale) or intrapulmonary (as seen with pneumonia or ARDS).^{5,6} A diffusion abnormality is infrequently the cause of hypoxemia in clinical practice and typically is only significant in the setting of tachycardia, high

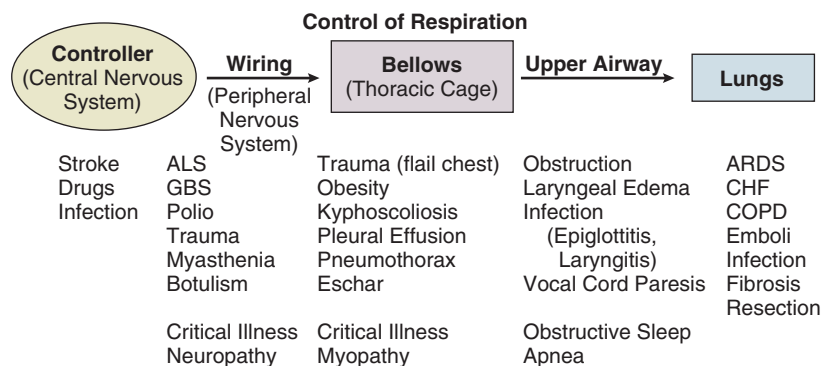

Figure 37.1 Control of respiration. ALS, amyotrophic lateral sclerosis; ARDS, acute respiratory distress syndrome; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; GBS, Guillain-Barré syndrome; Myasthenia, myasthenia gravis or the Eaton-Lambert myasthenic syndrome.

Box 37.1 Common Causes of Hypoxemic and Hypercapnic Respiratory Failure

Brain

Bulbar poliomyelitis
Central alveolar hypoventilation
Cerebrovascular accident
Cerebral malignancy
Drug overdose (e.g., narcotic, sedative/hypnotic)
Elevated intracranial pressure
Encephalitis and meningitis
Pontine herniation
Postoperative anesthetic depression

Spinal Cord

Amyotrophic lateral sclerosis
Cervical cordotomy
Guillain-Barré syndrome
Poliomyelitis
Spinal cord trauma

Neuromuscular System

Acute intermittent porphyria
Botulism
Cholinergic crisis
Curariform drugs
Electrolyte disorders (e.g., hypophosphatemia, hypomagnesemia)
Hypokalemic periodic paralysis
Multiple sclerosis
Myasthenia gravis
Myxedema
Neuromuscular blocking antibiotics (e.g., polymyxin, streptomycin)
Organophosphate insecticides
Peripheral neuritis
Polymyositis
Respiratory muscle fatigue—critical illness polyneuropathy/polyomyopathy
Tetanus

Upper Airway

Epiglottitis and laryngotracheitis
Large tonsils and adenoids
Obstructive sleep apnea
Postintubation laryngeal edema

Tracheal obstruction
Vocal cord paralysis

Thorax and Pleura

Chest wall burn with eschar formation
Chest wall trauma—flail chest
Kyphoscoliosis
Massive abdominal distention
Massive obesity
Muscular dystrophy
Large pleural effusion/pleural fibrosis
Pneumothorax
Rheumatoid spondylitis
Thoracoplasty

Cardiovascular System

Cardiogenic pulmonary edema
Left ventricular failure
Mitral stenosis
Biventricular failure
Fat embolism
Snake bite
Uremia
Volume overload
Pulmonary veno-occlusive disease

Lower Airway and Alveoli

Acute respiratory distress syndrome (ARDS)
Aspiration
Asthma
Atelectasis
Bronchiectasis
Bronchiolitis
Chronic obstructive pulmonary disease
Cystic fibrosis
Interstitial lung disease
Massive bilateral pneumonia
Near-drowning
Pancreatitis
Pulmonary contusion
Radiation lung injury
Sepsis
Smoke inhalation
Surgical resection of lung parenchyma

cardiac outputs, and when the diffusion capacity is below 25% of predicted.³

ASSESSMENT OF OXYGENATION

The hallmark of type 1 respiratory failure is hypoxemia, which is primarily assessed by the PAO_2 of an arterial blood gas (ABG). An estimate of the patient's oxygenation status can be obtained by measuring the oxygen saturation using a pulse oximeter. An appreciation of the sigmoid shape of the oxyhemoglobin dissociation curve allows for a rough estimation of the PAO_2 (Fig. 37.2). The curve will shift rightward or leftward in relation to changes in the pH, $Paco_2$, temperature, and PO_4^{-2} concentration.⁷ Determination of the ABG and knowledge of the exact FIO_2 allows for the calculation of the alveolar-arterial oxygen gradient³ (A-a gradient) using the formula $PAO_2 - PaO_2 = A-a$ gradient; thus,

$$PAO_2 = FIO_2(PB - PH_2O) - PaCO_2/R$$

where

- PAO_2 Partial pressure of oxygen in the alveolus
 PaO_2 Partial pressure of oxygen in the arterial blood

- FIO_2 Fraction of inspired oxygen
 PB Barometric pressure
 PH_2O Water vapor pressure at standard temperature and pressure
 $PaCO_2$ Partial pressure of carbon dioxide in the arterial blood
 R Respiratory quotient ($R = 0.8$)

The A-a gradient is FIO_2 dependent and will increase as the FIO_2 increases. Because of this FIO_2 dependency, some have preferred to evaluate oxygenation abnormalities by calculating the PAO_2/PAO_2 ratio, which is independent of the FIO_2 .³ For simplicity's sake, many individuals use the PAO_2/FIO_2 ratio as a measure of oxygenation abnormality. This value is used in the definition of ARDS and has gained wide-scale acceptance as a measure of abnormal oxygenation.⁸ The shunt fraction or venous admixture can also be calculated while a patient breathes 100% oxygen and has reached steady-state oxygenation.

HYPERCAPNIC RESPIRATORY FAILURE

Hypercapnic respiratory failure can be the result of a variety of disorders as listed in Box 37.1.⁹ Acute hypercapnic respiratory failure, also termed *acute ventilatory failure*, occurs when a patient's ABG reveals acute respiratory acidemia ($pH < 7.35$) with a $Paco_2$ greater than 50 mm Hg. This definition is not generally applicable to patients with severe chronic obstructive lung disease or neuromuscular disorders who have developed a compensatory metabolic alkalemia in response to their chronic hypercapnia. However, these patients may have acute exacerbations or comorbid conditions that cause them to decompensate into *acute-on-chronic respiratory failure*.

In steady-state conditions the rate of CO_2 production ($\dot{V}CO_2$) equals the rate of CO_2 elimination. Carbon dioxide elimination ($\dot{V}CO_2$) is equal to the alveolar ventilation (V_A) multiplied by the partial pressure of carbon dioxide in the alveolar gas ($PACO_2$). Thus, the equation for carbon dioxide production is $\dot{V}CO_2 = V_A \times PACO_2$. In the pulmonary capillary, carbon dioxide is readily diffusible through the endothelial and epithelial cell membranes down a substantial concentration gradient of approximately 45 to 50 mm Hg (normal pulmonary arterial CO_2 [$Paco_2$] versus essentially zero for the partial pressure of carbon dioxide in room air [$PICO_2$]) so that the alveolar and capillary blood partial pressures of CO_2 are equal ($PACO_2 = PaCO_2$).

Not all respired air is effective alveolar ventilation because some of the total tidal ventilation (V_T) ventilates nonperfused areas or dead space (V_D) (both anatomic and pathologic). This relationship between tidal volume, dead space volume, and alveolar volume can be expressed as³:

$$V_T = V_A + V_D \text{ or } V_A = V_T - V_D$$

The minute ventilation (\dot{V}_E) is equal to the sum of the dead space ventilation (\dot{V}_D) and the alveolar ventilation (\dot{V}_A): $\dot{V}_E = \dot{V}_D + \dot{V}_A$. Combining and rearranging terms from these various equations yields the following relationship of carbon dioxide production and alveolar ventilation with the $Paco_2$.³

$$PaCO_2 = \frac{\dot{V}CO_2}{V_T - V_D}$$

Therefore, elevated $PaCO_2$ can result from a combination of any of three clinical alterations: increased CO_2 production, decreased tidal ventilation, or increased dead space ventilation.⁹ Increased CO_2 production arises from hypermetabolic states such as exercise, fever, sepsis, burns, trauma, excessive carbohydrate intake, and hyperthyroidism.⁹ In isolation, these relatively common conditions rarely induce hypercapnic respiratory failure because the normal physiologic response to an elevated $PaCO_2$ is to increase minute (and therefore alveolar) ventilation to maintain eucapnia and a normal pH. Only those patients who are unable to increase their effective alveolar ventilation as a result of neuromuscular disorders affecting the muscles of respiration, the presence of excessive ventilation/perfusion (\dot{V}/\dot{Q}) mismatching, or increased dead space ventilation develop hypercapnic respiratory failure caused by elevated CO_2 production.

Ventilatory deficiencies, decreased tidal ventilation, and increased dead space ventilation that result in hypercapnic respiratory failure can be differentiated by using the A-a gradient equation. The $PAO_2 - PaO_2$ difference breathing room air is normally less than 10 to 15 mm Hg when simple alveolar hypoventilation is responsible for the hypoxemia noted on blood gas analysis. An increased $PAO_2 - PaO_2$ difference suggests a parenchymal lung process, usually associated with \dot{V}/\dot{Q} abnormalities, to account for the additional hypoxemia in these patients with hypercapnic respiratory failure.

Decreased tidal volume hypoventilation can be caused by disorders affecting any component of the “neuromuscular sequence” starting in the central nervous system (CNS) and ending at the muscles of respiration (see Fig. 37.1). Among the more common causes are CNS depressants such as narcotics and sedatives, which diminish respiratory drive; cerebral vascular disorders, especially those that involve the brainstem, which impair the efferent signals to breathe; and disorders of neuromuscular transmission such as myasthenia gravis and the paraneoplastic Eaton-Lambert myasthenic syndrome (Box 37.3).^{10,11} Abnormal respiratory mechanics can result from airflow obstruction, chest wall deformities,

and loss of lung volume. Disorders that increase the respiratory load, such as a circumferential chest burn eschar or flail chest, or impair function of the respiratory muscles, such as kyphoscoliosis, will also lead to hypoventilation.

ASSESSMENT OF VENTILATION

The hallmark feature of inadequate ventilation is the presence of an elevated $PaCO_2$ with or without the presence of hypoxemia.^{3,9} In the adult population the best method to detect an elevated $PaCO_2$ is with an ABG measurement. Non-invasive evaluation of ventilation in the critically ill adult, using end-tidal CO_2 ($PetCO_2$) measurements or transcutaneous CO_2 ($PtCCO_2$) determinations, is not as reliable as it is in the healthy adult or the neonate, respectively.⁷

CLINICAL MANIFESTATIONS

The risk factors for developing acute respiratory failure include the postoperative state, preexisting chronic illness, malnutrition, advanced age, morbid obesity, chronic bronchitis, and cigarette smoking. The clinical manifestations of respiratory distress may be subtle and nonspecific or may be obvious to even the untrained observer. The patient with respiratory distress may have an abnormal respiratory rate (too high or low) or display an irregular pattern of breathing. The patient with respiratory distress may evidence gasping ventilation, nasal flaring, or use of the accessory muscles of respiration. Intercostal retractions may be seen, and the patient may exhibit paradoxical respiratory movement. Typically, patients with acute respiratory failure, whether type 1 or type 2, will have altered heart rate and blood pressure. The majority will evidence a sympathetic response with tachycardia and hypertension, but patients may be hypotensive and bradycardic. Cardiac arrhythmias may be seen in both type 1 and type 2 respiratory failure. Patients with acute respiratory failure will usually be in distress and often appear apprehensive.^{2,9} Many will be diaphoretic and have altered mental status or level of consciousness. Hypercapnic patients may demonstrate signs of a respiratory encephalopathy including somnolence, coma, asterixis, seizures, tremors, or myoclonic jerks. Papilledema and congested conjunctivae may be present. Type 1 respiratory failure patients may appear cyanotic.⁹

Box 37.3 Causes of Decreased Respiratory Muscle Strength or Endurance

- Disorders of the phrenic nerve
 - Guillain-Barré syndrome
 - Poliomyelitis
- Respiratory muscle atrophy
- Disorders of neuromuscular transmission
 - Myasthenia gravis
 - Ventilator dependence
 - Malnutrition
 - Myopathy
 - Critical illness polyneuropathy/myopathy
- Altered diaphragmatic force-length relationship
 - Dynamic hyperinflation and diaphragmatic flattening

ACUTE RESPIRATORY DISTRESS SYNDROME

Since the initial 1967 description of acute catastrophic respiratory failure in 12 patients who were subsequently declared to have the acute respiratory distress syndrome, there has been a great deal of research and clinical study attempting to understand the mechanism of injury and improve the outcome of these critically ill patients.¹²⁻¹⁴ The hallmark of this disorder was the rapid onset of acute hypoxemic respiratory failure that was characterized by refractory hypoxemia despite the administration of high concentrations of supplemental oxygen; decreased pulmonary compliance; diffuse, bilateral pulmonary infiltrates; the absence of left-sided heart failure; and histologic evidence of alveolar damage

with hyaline membrane formation, which was followed by fibrosis of the lung.^{8,12,13} The subsequent 10 to 20 years of ARDS management were associated with extremely high mortality rates, at times approaching 90%, despite the provision of extremely aggressive supportive care.¹⁵⁻²⁰ Some of the initial clinical and basic investigations that attempted to improve the outcome of patients with ARDS were hampered by the lack of uniformly accepted definitions.²¹⁻²⁵ In 1994 an American-European Consensus Conference (AECC) defined acute lung injury (ALI) and ARDS in an attempt to eliminate confusion related to terminology for these conditions.^{21,22} The definitions are clinically based and regard ALI as a continuum with the more severe oxygenation abnormalities reflective of ARDS. Among the main benefits of the uniform definition would be improved communication and enhanced clinical trial design.

The AECC definition of ALI and ARDS was challenged and there were noted discrepancies between the clinical and pathologic findings in individuals felt to have died with ARDS.²⁵ Esteban and colleagues²⁵ found that one third of the people who died with a clinical diagnosis of ARDS did not have histologic evidence of diffuse alveolar damage on postmortem examination. In addition, diffuse alveolar damage, the hallmark pathologic finding of ARDS, was evident in 10% of patients who died without a clinical diagnosis of ARDS. A subsequent study evaluated the sensitivity and specificity of the Murray Lung Injury Score, the AECC definition of ARDS, and a Delphi definition that incorporated oxygenation abnormality, X-ray findings, clinical onset, compatible clinical scenario, and absence of left-sided heart failure for ARDS.²⁶ The combination of Lung Injury Score greater than 2.5 with either the AECC definition or the Delphi definition of ARDS resulted in the best combination of sensitivity and specificity. Since its introduction, the AECC definition has been used by the vast majority of clinical trials evaluating new treatment strategies for patients with ARDS, particularly those conducted by the ARDS Network investigators, supported by the U.S. National Heart, Lung, and Blood Institute of the National Institutes of Health.²⁷⁻²⁹ In 2011 experts from the European Society of Intensive Care Medicine, the American Thoracic Society, and the Society of Critical Care Medicine met in Berlin and proposed a new definition for staging ARDS as mild, moderate, or severe, based on the oxygenation impairment measured on a minimum of 5 cm H₂O positive end-expiratory pressure (PEEP) (10 cm H₂O for severe).³⁰ The new Berlin definition did not drastically differ from the prior AECC definition, but it clarified several important concepts:

1. Timing—patients with ARDS should be identified within 72 hours of a recognized risk factor and nearly all patients should be identified within 7 days.
2. Chest imaging—bilateral opacities consistent with pulmonary edema are seen on chest radiograph or chest computed tomography (CT) scan.
3. Origin of pulmonary edema—ARDS may be present in the setting of coexisting cardiogenic edema or volume overload if in the opinion of the treating physicians the respiratory failure is not fully explained by these conditions and there is a recognized risk factor for ARDS. In the absence of a recognized risk factor for ARDS there should be some objective assessment of cardiac function

such as echocardiography or pulmonary capillary wedge pressure measurement.

4. Oxygenation—because PEEP can affect the $\text{PaO}_2/\text{FiO}_2$ ratio there should be a minimum of 5 cm H₂O PEEP and 10 cm H₂O in those patients with severe ARDS ($\text{PaO}_2/\text{FiO}_2 < 100$).³⁰

The Berlin definition for ARDS eliminates the use of the term “acute lung injury” to classify the severity of lung injury and defines mild ARDS as a $\text{PaO}_2/\text{FiO}_2$ 300 or less but greater than 200, moderate ARDS as a $\text{PaO}_2/\text{FiO}_2$ 200 or less but greater than 100, and severe ARDS as a $\text{PaO}_2/\text{FiO}_2$ 100 or less, with mortality rates associated with the different stages 27%, 32%, and 45%, respectively.³⁰

To date there is no specific laboratory test that is pathognomonic for the diagnosis of ARDS.^{8,21,27} All of the current definitions for ARDS require the presence of bilateral pulmonary infiltrates on chest imaging, but interpretation is not always straightforward.^{21,31} When 21 experts were given 28 chest radiographs to evaluate for the presence of bilateral pulmonary infiltrates, they only agreed 43% of the time, and one third of the time five or more individuals differed in their interpretation.²⁹ The range of ALI/ARDS diagnoses was from 36% to 71%.³²

RISK FACTORS

It has been recognized that ARDS may arise in association with a number of clinical conditions or risk factors, with sepsis being the most common (Box 37.4).^{8,18,21,27,33-37} Various studies report that approximately 5% to 40% of septic patients will develop ARDS.^{8,18,36} Shock (prolonged hypotension) and the systemic inflammatory response syndrome (SIRS) are also common risk factors. Other frequently encountered clinical risk factors include multiple emergency transfusions; aspiration injury; near-drowning; pancreatitis; trauma (particularly lung contusion, fat emboli from long bone fractures); burns; cardiopulmonary bypass; and disseminated intravascular coagulation (DIC). These clinical risk factors are synergistic, and when more than one of the clinical risk factors is present, the likelihood of ARDS is greater than just the sum of the collective risk factors.^{8,17} The clinical risk factors associated with the development of ARDS appear to greatly influence the expected outcome. Whether ALI and ARDS arise from a direct pulmonary

insult or from an extrapulmonary cause impacts the subsequent response to PEEP and ventilatory support (Box 37.5).¹⁹ Age also has an impact on the likelihood for ARDS development.³⁸ Older individuals have a greater likelihood of developing ARDS from most of the risk factors noted earlier. In the setting of trauma the risk for ARDS seems to peak in the sixth and seventh decades and then declines.³⁸

Negative pressure (postobstructive) pulmonary edema (NPPE or POPE) is a type of noncardiogenic pulmonary edema that can manifest as ARDS.³⁹ It is rare (five cases reported from a large tertiary medical ICU in 4 years),⁴⁰ can range in severity from mild hypoxemia treated with low-flow supplemental oxygen to profound hypoxemia requiring mechanical ventilation, and may even present as alveolar hemorrhage.⁴¹⁻⁴⁵ It is believed to be caused by increased vascular permeability resulting in alveolar and capillary damage from large levels of negative intrathoracic pressure generated by attempting to inspire against an occluded airway or airway obstruction.^{46,47} This leads to a protein-rich alveolar exudate impairing gas exchange in mild-to-moderate cases and leaking of capillary blood into the alveoli in more severe circumstances. Most of the reported cases are related to surgical procedures: thyroidectomy,^{48,49} septorhinoplasty,⁵⁰ tonsillectomy/adenoidectomy,⁵¹ mandibular open reduction and internal fixation,⁵² or cryosurgery for a tracheal obstruction.⁵³ Nonoperative conditions leading to NPPE have included laryngospasm,^{54,55} occlusion of an endotracheal tube,^{56,57} excessive tube thoracostomy suction pressure,⁵⁸ nonlethal hanging,⁵⁹ and even hiccups.^{60,61} The common element is the rapid relief of a large airway occlusion. Patients often have no underlying cardiopulmonary disorders. NPPE may account for a small percentage of immediate postoperative extubation failures, particularly if an unrecognized mainstem intubation is present in an awake and spontaneously breathing patient. Clinical manifestations of hypoxemia and respiratory distress may be delayed up to 6 hours.⁴⁷ Therapy is supportive with

supplemental oxygen and, if needed, positive-pressure ventilation (invasive or noninvasive).

Elevated intracranial pressures, either from traumatic brain injury or intracerebral hemorrhage, or status epilepticus can induce an ARDS-like clinical syndrome termed neurogenic pulmonary edema (NPE).^{62,63} Although the exact mechanisms are not clear, an abrupt and massive release of catecholamines from injured neuronal tissues is thought to act directly on the lung parenchymal vasculature to promote a “capillary leak” of a protein-rich exudate as well as an increase in pulmonary vascular resistance⁶⁴ in addition to inducing a neurohumoral (takotsubo) cardiomyopathy.⁶⁵⁻⁶⁷ The cardiomyopathy has the distinctive echocardiographic feature of ventricular apical ballooning and can persist for months.⁶⁸

INCIDENCE AND PREVALENCE

The exact incidence and prevalence of ARDS has been variable and related to definitions used (Box 37.6).^{8,38} Early reports suggested that there were 150,000 patients with ARDS each year in the United States.^{8,33,36,69} This statistic led to an estimated incidence of 75 cases per 100,000 population. Proposed estimates have suggested that the incidence of ARDS ranges from 1.5 to 64 cases per 100,000 population.^{38,69,70} A recent study evaluated the incidence and outcome of ALI in mechanically ventilated patients aged 15 or older cared for at 21 hospitals in and around King County, Washington, over a 15-month observation period.³⁸ The crude incidence of ALI was 78.9 per 100,000 person-years, and the incidence of ARDS was 58.7 per 100,000 person-years. On the basis of their results, the authors estimated the annual number of U.S. episodes was 332,100 cases of ARDS. The authors noted that increasing age was associated with an increased incidence and mortality rate in ARDS. A recent prospective observational study using the AECC definition and lung protective ventilatory support strategies in Spain (the ALIEN study) reported an incidence of 7.2 per 100,000 population per year for ARDS with an ICU and hospital mortality rate of 42.7% and 47.8%, respectively.⁷¹

Box 37.5 Common Pulmonary and Extrapulmonary Causes of ARDS

Direct Pulmonary Causes

- Pneumonia
- Acid aspiration
- Inhalational lung injury
- Lung contusion
- Chest trauma
- Near-drowning

Extrapulmonary Causes

- Sepsis—systemic inflammatory response syndrome
- Shock—hypotension
- Pancreatitis
- Trauma (fat embolism)
- Post cardiopulmonary bypass
- Massive transfusion therapy
- Burns
- Elevated intracranial pressure (traumatic brain injury, intracerebral hemorrhage)

Box 37.6 Incidence of ARDS

CLINICAL MANIFESTATIONS

When ARDS becomes clinically apparent, the patient is usually noted to be in significant distress manifesting dyspnea, tachypnea, visible signs of respiratory distress, and increased work of breathing.^{8,23,33,36} The typical presentation is manifest as an acute catastrophic complication in a patient who has one or more of the clinical risk factors for the development of this form of ARDS. The precipitating injury need not directly involve the pulmonary system.^{8,36,72} Past definitions have emphasized the need to exclude patients with previous or known chronic pulmonary or cardiovascular diseases.^{19,21,27} The AECC definition excluded patients with elevated left-sided heart filling pressures and chronic infiltrative lung disease as the cause of the radiographic or physiologic alterations, but the new Berlin definition will allow for the concomitant presence of ARDS and cardiac edema/volume overload as long as the predominant process is thought to be ARDS.^{21,30}

The hallmark of ARDS is the presence of hypoxemia despite the administration of high concentrations of inspired oxygen, evidence of an increase in the shunt fraction, a decrease in pulmonary compliance, and an increase in the dead space ventilation.^{8,24,30} The chest radiographic manifestation of ARDS is the presence of diffuse, bilateral pulmonary infiltrates with a normal cardiac silhouette. Recent reports have cautioned that even among trained experts there is often disagreement concerning the interpretation of the chest radiograph.^{31,29,69,73} Chest CT has also demonstrated that the radiographic injury is not homogeneous and has a predominance in the dependent portions of the lung.^{8,43} It is important to remember that ARDS is a clinical syndrome and the diagnosis is made clinically, not on the basis of a single radiograph, ABG analysis, or laboratory test.

PATHOLOGIC MANIFESTATIONS

Typically, type 1 alveolar cells compose the major gas exchange surface of the alveolus and are integral to the maintenance of the permeability barrier function of the alveolar membrane.⁸ Type 2 pneumocytes are the progenitors of type 1 cells and are responsible for surfactant production and homeostasis.⁸ During ARDS there is damage to the capillary endothelial and the alveolar epithelial cells.⁸ Cellular injury and alteration of the normal barrier function results in a permeability defect that gives way to flooding of the alveoli with protein-rich fluid and inflammatory cells.^{8,33,74} This results in the alteration of pulmonary mechanics, physiology, and gas exchange.^{8,74} There is alteration of surfactant that results from damage to the type 2 pneumocyte and from the inactivation and dilution of alveolar surfactant from the protein and fluid that have entered into the alveolar space, respectively.^{75,76} Surfactant dysfunction can lead to atelectasis and a further reduction in pulmonary compliance.^{8,75-78} In addition, dysfunction of the alveolar epithelial cells can impair the resorption of fluid from the alveolar space, which augments the parenchymal injury process and gas exchange abnormalities.^{8,79}

The observed pathologic findings in ARDS depend on the timing of the tissue sampling. During the initial stages of clinically evident lung injury there is histologic evidence of diffuse alveolar damage.⁸ Histologic features of the injury

include microthrombi composed of platelets and white blood cells within the capillary lumen, denudation of the alveolar epithelial lining cells, swelling of the capillary endothelial cells, interstitial and alveolar infiltration by polymorphonuclear leukocytes (PMNLs), and hyaline membrane formation within the alveoli.⁸ Grossly, the lungs appear heavy and wet. Later, areas of type 3 collagen deposition with fibrosis will be present.⁷⁹ An intense inflammatory reaction involving PMNLs, activated monocytes, macrophages, and endothelial cells is present in the fibroproliferative phase of lung injury.^{76,80,81} Pro- and anti-inflammatory molecules produced by these activated cells may be found in the circulating blood and bronchoalveolar lavage (BAL) fluid.⁸¹⁻⁸³ This phase may be followed by fibrosis, but this fibrosis does not appear to have the same permanence as typical fibrosis would have and may actually resolve over time in survivors of the injury.⁸⁴

PATHOPHYSIOLOGY

ARDS may develop as a result of epithelial or endothelial cell injury.^{8,13,85,86} Both sites of injury and cells are important for maintenance of normal barrier function and are capable of initiating an inflammatory response. In the majority of clinical settings the initial site of the ARDS involves the capillary endothelial cell, which may be the initial manifestation of a “panendothelial cell injury” resulting from SIRS.⁸³ Endothelial cell injury compromises the integrity of the vascular barrier and results in transudation of fluid and inflammatory mediators into the interstitial tissues and ultimately into the alveoli.^{8,13} The frequent occurrence and early involvement of lung dysfunction as a component of multiple organ dysfunction/failure lends support to the hypothesis of a panendothelial cell injury as one of the target injuries in the setting of SIRS.⁸⁷

The complex pathophysiologic processes that culminate in the production of ARDS involve a delicate balance between the body's proinflammatory and anti-inflammatory responses to the inciting clinical event.^{83,87} The balance that exists between the various inflammatory molecules or mediators and the endogenous compensatory responses evoked by the inflammatory response will dictate whether or not lung injury and other forms of organ dysfunction will develop.⁸¹ The ensuing interaction between SIRS and the compensatory anti-inflammatory response syndrome (CARS) will thus determine whether a patient successfully deals with an injury or is predisposed to develop organ dysfunction (excessive SIRS response) or immunosuppression and infectious complications (excessive CARS response).^{83,87} This mixed antagonistic response syndrome (MARS) has tremendous impact on the fate of the critically ill patient.⁸⁷

MANAGEMENT STRATEGIES

Basic management strategies for patients with ARDS are listed in [Box 37.7](#).^{8,18,21,23,33,36,88} Initial attention must be directed to providing lung protective ventilator support and identification of the predisposing underlying clinical risk factor(s) or condition(s), and there should be specific treatment directed at the underlying or predisposing disorder.^{8,21-23} The recognition of sepsis and infection as frequent

Box 37.7 Basic Management Strategies for Patients with ARDS

Identify and treat underlying/predisposing cause of ARDS
 Ventilatory support
 Lung protective ventilatory support strategy
 Application of PEEP (per ARDSnet protocol)
 Restore and maintain hemodynamic function
 Conservative fluid replacement strategy using goal-oriented approach
 Vasopressor and inotropic support as needed to meet goals
 Prevent complications of critical illness
 Stress ulcer (stress-related mucosal disease) prophylaxis
 Preventive strategies for PE and DVT
 Prevent infections such as ventilator-associated pneumonia (VAP)
 Control glucose and metabolic function
 Prevent development of multiple organ dysfunction/failure
 Ensure adequate nutrition
 Avoid oversedation and medication errors
 Use of weaning protocol with spontaneous breathing trials when ready to wean
 Cautious use of steroids for fibroproliferative phase (avoid if patient has received neuromuscular blocking drugs)

ARDS, acute respiratory distress syndrome; DVT, deep venous thrombosis; PE, pulmonary embolism; PEEP, positive end-expiratory pressure.

causes of ARDS should prompt an aggressive search for undiagnosed foci of infection and the administration of appropriate antimicrobial treatment and use of surgical drainage procedures as indicated.^{15,17,89}

The cornerstone of supportive management is the provision of mechanical ventilatory support.^{8,21-23} Recent experimental and clinical data report significant survival benefit from the use of lung protective ventilatory support strategies.^{90,91} The primary goal of this support is to improve oxygenation and ensure that the lung is allowed to heal and avoid further injury. Use of nonprotective ventilatory support strategies may have a role in the persistent proinflammatory response and the development of multiple organ dysfunction syndrome (MODS) and multiple organ failure (MOF).⁹⁰⁻⁹³

MECHANICAL VENTILATION

See Chapter 11 for a more detailed discussion of mechanical ventilatory support in the management of patients with ARDS. Over the past 20 years there has been increasing recognition that the ventilatory support strategy used in the management of patients with ARDS may produce or augment lung injury or impair the healing process (Box 37.8).⁹⁴⁻⁹⁸ Results of experimental animal studies demonstrated clinical, physiologic, and histologic abnormalities similar to those observed in patients with ARDS when animals with normal lungs were ventilated with large tidal volumes or were given high inflation pressures.⁹⁵⁻¹⁰¹ The alveolar overdistention produced by these ventilatory modes was felt to be the critical element in production of the lung injury.⁹⁵⁻⁹⁸ Lung injury could result from the administration

 Biotrauma
 Barotrauma
 Air embolism/translocation

of large tidal volumes or the administration of positive pressure or negative pressure breaths that were sufficient to produce alveolar overdistention (termed *volutrauma*).⁹⁷⁻¹⁰² Other mechanisms that could potentially result in lung injury were the repetitive recruitment-derecruitment of distal airways (termed *atelectotrauma*) and alveoli or the disruption of alveoli resulting in translocation of organisms or air emboli.^{97,98} Alveolar overdistention can also give rise to systemic inflammatory molecules that may contribute to the SIRS response and drive the development of MODS/MOF.^{92,98} This has been termed *biotrauma*.⁹⁸ Interestingly, the lung injury produced by high inflation pressures or large tidal volumes in these experimental models could be ameliorated by the addition of therapeutic amounts of PEEP.^{97,98} Subsequent human studies have evaluated the distribution of the radiographic lung injury in ARDS patients as determined by the use of CT scans of the chest and have noted the dependent nature of the injury.^{74,103} The injury to the lungs was not diffuse and homogeneous as once believed. These dependent areas of injury comprised regions of alveolar flooding from the gravitational accumulation of lung water, areas of lung injury, and normal lung regions. The relatively normal ventral (nondependent) lung has been referred to as the “baby lung,” and the injured (dependent) lung has been called the “sponge lung.”^{32,103} With the use of higher tidal volumes, PEEP, or high distending pressures, there was evidence of alveolar overdistention, particularly in the areas of normal lung. A multicenter trial of low versus traditional tidal volume ventilation in patients with ARDS demonstrated increased proinflammatory cytokines in the serum and BAL fluid of patients ventilated with the larger traditional tidal volumes, supporting the concept of biotrauma from alveolar overdistention.⁹² Pulmonary barotrauma (pneumomediastinum, pneumopericardium, pneumoperitoneum, pneumothorax, subcutaneous emphysema, pulmonary interstitial emphysema, and air embolism) is a well-recognized complication of ventilatory support that has been reported in 7% to 15% of patients with ARDS.¹⁰⁴

The landmark study by NHLBI ARDS Network compared low tidal volumes (6 mL/kg of ideal body weight) against conventional tidal volumes (12 mL/kg of ideal body weight).⁹⁴ A protocol governed the use of PEEP according to the Fio_2 required to meet the oxygenation goals. A weaning protocol was used once the patient was on a reduced amount of ventilatory support. The trial was terminated after 861 patients were enrolled, following the determination of a significant (22% relative reduction) decrease in mortality rate associated with the use of low tidal volumes (39.8% vs. 31%; $P = 0.007$). A significant difference occurred between the low and high tidal volume groups in length of

stay, ventilator days, and development of MODS.⁹⁴ No difference occurred in the development of barotrauma between the two ventilator support strategies. On further analysis, this survival benefit was present irrespective of the patient's body mass index (BMI).¹⁰⁵

The use of lower tidal volumes typically results in a controlled hypoventilation or permissive hypercapnia and can lead to hypercapnic acidosis.¹⁰⁶ Some experimental animal models of lung injury suggest that hypercapnic acidosis may be beneficial to the lung and produce less lung injury as measured by extravascular lung water (Box 37.9).¹⁰⁵ Other reports have detailed potentially harmful effects of hypercapnia on epithelial and endothelial barrier function, lung edema, edema clearance, innate immunity, and host defenses.¹⁰⁷

PEEP is a major component of the ventilatory support strategy and may actually have a direct therapeutic role in the prevention of ventilator-induced lung injury (VILI), as noted in some of the experimental models of VILI.^{8,96,108-117} PEEP is beneficial in the recruitment of atelectatic lung units and prevention of recruitment-derecruitment, and it increases the functional residual capacity (FRC), decreases the shunt fraction, and allows for a reduction to a less toxic FiO_2 while still maintaining adequate oxygen saturation and tissue oxygen delivery.^{110,114-116,118} The application of the "right amount" of PEEP has recently taken on a more sophisticated approach. The ability to construct a pressure-volume curve to reflect the compliance of the patient's lung has allowed for the identification of both the lower and upper inflection points (Fig. 37.3).¹¹⁷ Maintaining a PEEP level above the lower inflection point should potentially avoid the repetitive opening and closing of alveoli and the development of shear forces from the recruitment-derecruitment process, which may participate in the production or propagation of lung injury. If too much PEEP is applied, there may be overdistention of alveoli, which can potentiate volutrauma or barotrauma and have adverse consequences on pulmonary mechanics, hemodynamic function, and lung healing. Constructing pressure-volume curves to determine the "best PEEP" is a difficult undertaking and requires the patient to be heavily sedated or paralyzed and the use of a calibrated super syringe. Determining the

Figure 37.3 Pulmonary volume-pressure curve. PEEP, positive end-expiratory pressure. (Modified from Hospital Pulmonary Disease Board Review Manual 2000;7:7.)

precise lower inflection point on the inspiratory inflation curve is difficult, and the compliance curves may change (along with the inflection points) over time as the patient's lung compliance changes. To simplify the determination of PEEP, the ARDS Network ventilatory support protocol used a monogram for PEEP based on the FiO_2 requirements and the goal of maintaining a PAO_2 between 55 and 80 mm Hg.⁹⁴ For the protocol, end-inspiratory plateau pressure was kept lower than or equal to 30 cm H₂O and the pH was maintained in the 7.30 to 7.45 range. Despite the demonstrated significant improvement in mortality rates associated with this protocol, some felt that additional benefit could be seen with the use of higher levels of PEEP. A subsequent large, prospective, randomized controlled trial conducted by the ARDS Network evaluated the PEEP protocol from the initial trial (PEEP levels from 5 to 24 cm H₂O) versus higher levels of PEEP.¹¹⁹ During the study there was a change to a higher PEEP strategy to ensure a difference in the amount of applied PEEP between the two treatment arms. No significant difference in deaths before discharge home, breathing without assistance by day 28, ventilator-free days, ICU-free days, organ failure-free days, or barotrauma was found.¹¹⁹ Several studies have prospectively evaluated the benefits of higher versus lower PEEP strategies in the management of patients with ARDS, and a recent meta-analysis has failed to demonstrate a significant short-term mortality rate benefit associated with the use of higher PEEP.¹¹⁹⁻¹²³

PEEP has the potential to have profound hemodynamic consequences in selected patients and clinical circumstances, and it is important to closely monitor patients with hemodynamic, echocardiographic, or other sophisticated monitors if there is a question of the adequacy of cardiac function when PEEP is applied.^{6,109-111} Right-to-left shunting through a patent foramen ovale can occur in up to a third of patients with severe ARDS, and increasing PEEP may not produce the expected oxygenation benefits in these individuals.¹²⁴ The effect of PEEP may not be the same in the supine and prone positions. Apparently there is an enhanced ability to recruit alveoli when the patient is in the prone position as compared with the supine position when the patient is on the same amount of PEEP.¹²⁵ There may be a different responsiveness to the use of PEEP depending on whether the ARDS results from a direct pulmonary injury or a nonpulmonary process that gives rise to ARDS.³²

Despite the survival benefits demonstrated by the use of the lung protective ventilatory support strategy, there has not been universal adoption of this technique of ventilatory support for all patients with ARDS. Reasons for this slower than expected incorporation into daily practice are many and varied and certainly go beyond lack of awareness. Young and coworkers¹²⁶ reported on the tidal volume used to ventilate ARDS patients at three large New England university hospitals. Prior to the publication and subsequent education of the ARDS Network results, the tidal volume averaged 12.3 mL/kg predicted body weight (9.8 mL/kg measured body weight). After the publication, the tidal volume dropped to 10.6 mL/kg predicted body weight (8 mL/kg measured body weight).

A multicenter French study has reported that the use of neuromuscular blockade with cisatracurium over the initial 48 hours of severe ARDS was associated with improved 90-day survival and longer time off ventilator support in contrast to conventional ventilator management.¹²⁷ A prior study by these investigators noted decreased inflammatory response associated with the use of neuromuscular blockade in patients with ARDS.¹²⁸ Although there is always a risk for prolonged neuromuscular weakness after use of neuromuscular blocking drugs, as well as in critical illness, there are many potential benefits in support of using neuromuscular blocking agents early in severe ARDS.¹²⁹ Some of these potential benefits include better patient-ventilator synchrony and interaction, less VILI (barotraumas, atelectrauma, biotrauma), better recruitment effect from administered PEEP, and decreased oxygen consumption.^{129,130}

FLUID MANAGEMENT AND VASOACTIVE SUPPORT

There has been controversy regarding the approach to fluid management and oxygen delivery in the critically ill patient with ARDS.¹³¹⁻¹⁴² Patients with ARDS often require aggressive management to restore and maintain appropriate hemodynamic function.¹⁴³⁻¹⁴⁴ The SAFE trial demonstrated that resuscitation with saline is as beneficial as resuscitation with albumin in critically ill patients with shock.¹⁴⁵ Correcting shock and hemodynamic derangements in patients with ARDS is important because these are potential causes for the lung injury and may result in organ dysfunction/failure.¹⁴⁴ Several studies have reported increased survival associated with low pulmonary capillary occlusion pressure in the setting of ARDS.^{131,133} Concern for compromised organ perfusion and predisposition to the development of organ system dysfunction and the development of MODS/MOF led to additional studies from the ARDS Network to evaluate a liberal versus conservative fluid replacement strategy (Fluid and Catheter Treatment Trial [FACTT] study).¹⁴⁶ In addition, this trial was designed to evaluate the utility and safety of using a pulmonary artery (PA) catheter to guide volume replacement as opposed to a central venous catheter.¹⁴⁷ The safety and potential benefits of using PA catheters in the critically ill has been an area of controversy since the 1990s.¹⁴⁸ In 1996, Connors and coworkers reported a lack of benefit and possible harm associated with the use of PA catheters in critically ill patients in the SUPPORT database.¹⁴⁹

In a prospective, randomized controlled trial of PA catheters versus no PA catheters in the management of 676 adult

patients with shock or ARDS, there was no difference in organ failure-free days, ventilator-free days, vasopressor-free days, or days in the ICU or hospital.¹⁵⁰ This trial did not have an algorithm to direct management based on the hemodynamic data obtained from the use of the PA catheter. The ARDS Network trial evaluated liberal versus conservative fluid management on the basis of the central venous catheter (central venous pressure [CVP]) data versus PA catheter (PA occlusion pressure [PAOP]) data in 1000 patients with established ARDS.¹⁴⁷ The use of a PA catheter did not significantly change 60-day survival or days of unassisted breathing in comparison with the use of a central venous catheter.¹⁴⁷ There was no difference between the groups in lung or renal function, use of vasopressors, renal replacement therapy, or hypotension. The PA catheter group did have twice as many catheter-related complications, predominantly in the form of arrhythmias, compared with the central venous catheter group.

The liberal fluid management arm of the FACTT study had an average net gain of almost 7 L over the first 7 days, whereas the conservative fluid management group averaged a loss of 136 mL over 7 days of cumulative fluid balance.¹⁴⁶ The use of the conservative fluid management strategy was associated with a significant improvement in oxygenation index and lung injury score and increased the number of ventilator-free days compared with the more liberal strategy. There was no difference in the development of shock or the need for renal replacement therapy between the two fluid management strategies.¹⁴⁶

PREVENTION OF COMPLICATIONS OF CRITICAL ILLNESS

ARDS patients are also at risk for the complications that commonly complicate the course of the critically ill. Most of these complications are preventable, and prophylactic strategies should be employed whenever possible. Common complications include deep venous thrombosis and pulmonary embolism, stress-related gastrointestinal hemorrhage, ventilator-associated pneumonia (VAP) and nosocomial infections, metabolic abnormalities, critical illness polyneuropathy, and malnutrition.¹⁵¹⁻¹⁵⁵ Anticipation and prevention of these complications are vitally important. Prophylactic strategies to prevent stress-related mucosal disease and gastrointestinal bleeding using H₂ blockers, proton pump inhibitors, or possibly early enteral nutrition should occur in all patients unless otherwise contraindicated.^{155,156} Deep vein thrombosis and pulmonary embolism prophylaxis should also be administered unless there are contraindications.¹⁵⁶ The use of enteral nutrition may be valuable in an attempt to prevent stress-related gastrointestinal bleeding and prevent translocation when normal barrier function of the gastrointestinal mucosa is compromised.^{155,157-160} Nutritional support may also be important to maintain the proper level of immune function and potentially to prevent the development of malnutrition in the catabolic critically ill patient. The use of enteral formulas designed to enhance the immune response with increased amounts of arginine, glutamine, or selected fatty acids remains controversial. The use of enteral formulas with increased amounts of eicosapentaenoic acid and γ -linolenic acid has been shown to improve organ dysfunction and improve oxygenation in clinical trials but has not been demonstrated to improve

survival in patients with ARDS.^{161,162} The ARDS Network found that the use of twice daily enteral supplementation with ω -3 fatty acids, γ -linolenic acid, and antioxidants did not improve clinical outcome and was associated with a greater amount of diarrhea.¹⁶³ A subsequent (EDEN) randomized trial by the same investigators found that ARDS patients who received trophic (minimal enteral) feeding did just as well and had less gastric residual volume, vomiting, and constipation and a lower blood sugar and insulin requirement than the patients who received full enteral feeding over the first 6 days.¹⁶⁴ For those patients who do not tolerate enteral nutrition, waiting to provide parenteral nutritional support for up to 8 days was found to be well tolerated, was safer, had fewer complications, and was associated with a faster recovery in critically ill adult patients.¹⁶⁵

A major goal of management should be the prevention of nosocomial or secondary infections/sepsis and multiple organ dysfunction/failure because these two conditions are currently responsible for the high mortality rate seen in patients with ARDS.^{18,89,151-153} VAP is a frequent complication in critically ill ventilated patients. As previously mentioned, prevention of VAP should be a primary management goal for patients with ARDS. Detection of a complicating VAP can be difficult in the setting of the pulmonary radiographic infiltrates seen in patients with ARDS. Diagnosis of VAP and identification of the offending pathogen often require the use of bronchoscopy with BAL or protected specimen brushes coupled with semiquantitative culture analysis.^{151,153} Recent data suggest that identifying the soluble triggering receptor expressed on myeloid cells (sTREM) may be beneficial in the detection of VAP but does not identify the specific etiologic organism.¹⁶⁶ European investigators have been enthusiastic about the technique of selective digestive decontamination (SDD) as a method to decrease nosocomial lung infections in the critically ill patient.¹⁶⁷ Keeping the head of the bed elevated above 30 degrees is also effective at preventing VAP.¹⁵⁶ Additional measures designed to decrease the development of VAP include continuous subglottic suction, coated endotracheal tubes, closed suction systems, and kinetic therapy.¹⁵⁶ Development of complications has been associated with increased morbidity rate, length of stay, cost of care, and possibly mortality rate.^{155,156}

Pulmonary barotrauma has been reported to develop in approximately 7% to 15% of patients with ARDS.¹⁰⁴ When a pneumothorax is detected in a mechanically ventilated patient, prompt recognition and chest tube insertion are required to prevent the development of tension physiology.¹⁰⁴

STRATEGIES TO IMPROVE OXYGENATION

In patients with severe ARDS and persistent hypoxemia various strategies have been developed in an attempt to improve oxygenation and lessen FiO_2 requirements. Included in these strategies are recruitment maneuvers, prone positioning, sighs, surfactant replacement therapy, partial liquid ventilation, inhaled nitric oxide, and enhanced edema clearance.^{125,168-194} These techniques remain investigational at this time and should be subjected to rigorous evaluation to adequately determine their ability to improve outcome for patients with ARDS. Importantly, the use of

higher tidal volumes (12 mL/kg ideal body weight) in the ARDS Network trial was associated with an improvement in oxygenation but a significantly decreased survival in patients with ARDS.⁹⁴

Recruitment maneuvers represent an attempt to open the atelectatic distal airways and alveoli on the border of the collapsed flooded alveoli that compose the dependent area of radiographic lung injury.⁹⁸ Some experts believe that this maneuver should precede the provision of PEEP and ventilator support in the early phases of ARDS.¹⁹⁵ The maneuver is accomplished by increasing the PEEP to 35 to 50 cm H_2O and holding that level of pressure for 30 seconds. The ARDS Network attempted to define the value of a recruitment maneuver in 43 patients with ARDS by randomly assigning them to a recruitment maneuver with 35 to 40 cm H_2O for 30 seconds versus a sham recruitment maneuver.¹⁷⁹ The recruitment maneuver was assessed on the basis of a sustained improvement in oxygenation as judged by the ability to titrate PEEP/ FiO_2 on the basis of the network algorithm and changes in lung compliance. There was no significant difference in the magnitude or duration of the oxygenation effect, compliance, or change in PEEP/ FiO_2 titration. The group that received a recruitment maneuver did have a greater decrease in blood pressure during the maneuver. Other studies have reported that recruitment maneuvers are well tolerated from a hemodynamic standpoint and are not associated with increased cytokine release.¹⁸⁰

Patients with ARDS may improve their oxygenation abnormalities when they are placed in the prone position.¹⁶⁸⁻¹⁷⁵ This position may be more physiologic for most mammals and result in improved secretion removal, better ventilation/perfusion matching, and better aeration of the dorsal lung units.¹⁷² The prone position may also prevent the heart from collapsing the left lower lobe and enhance the recruitment effects of PEEP by stabilizing the more flexible ventral chest wall.¹⁷² Prone positioning may also unload the right ventricle in the setting of severe ARDS.¹⁷³ A number of trials have demonstrated an improvement in oxygenation during and after being placed in a prone position.¹⁷⁰⁻¹⁷⁴ One prospective randomized trial designed to demonstrate survival advantage failed to do so.¹⁷⁵ A number of potential complications can result from the process of changing the patient from a supine to a prone position.^{183,184} Included in the list of potential complications are tube/catheter malposition/problems, pressure sores, blindness, and difficulty with patient assessment and resuscitation.^{183,184} Prone positioning should be considered in patients with low risk for such a position change who require high FiO_2 despite optimization of ventilator strategy.

INHALED NITRIC OXIDE

Inhaled nitric oxide is a bronchial and vascular smooth muscle dilator that also decreases platelet adherence and aggregation.^{173,196} It has been shown to improve oxygenation by improving ventilation/perfusion relationships in the lung.^{185,196,197} A reduction in PA pressure and pulmonary vascular resistance also occurs. These beneficial pulmonary effects are associated with minimal systemic effect from the inhaled nitric oxide because it is rapidly inactivated when the nitric oxide enters the circulation and is taken

up by red blood cells. Multiple prospective, randomized, placebo-controlled clinical trials failed to demonstrate an improvement in survival despite the early improvement in oxygenation associated with the administration of inhaled nitric oxide.^{191,193,194}

SURFACTANT REPLACEMENT THERAPY

Surfactant abnormalities are present in patients with ARDS related to decreased production, inactivation by alveolar proteins and proteolytic enzymes, and dilution by the alveolar fluid.¹⁷⁸ Theoretically, surfactant replacement should produce a survival benefit, just as it does in the infant respiratory distress syndrome.^{177,178} Anzueto and colleagues¹⁷⁶ reported no difference in hemodynamic function, oxygenation, length of stay, duration of mechanical ventilation, and survival in 725 sepsis-induced ARDS patients who were prospectively randomized into a placebo-controlled trial of Exosurf (artificial surfactant) versus placebo. The researchers believe that the lack of associated surfactant proteins might account for the lack of efficacy. Trials are continuing to evaluate recombinant forms of surfactant replacement that include surfactant proteins.¹⁷⁷ A meta-analysis from a group of small trials evaluating recombinant surfactant protein C replacement in patients with ARDS noted an improvement in oxygenation but no survival benefit.¹⁷⁷ To date there has not been a survival benefit associated with the use of surfactant replacement therapy in adults with ARDS.^{77,78,173}

ENHANCED EDEMA CLEARANCE

Accumulated fluid in the alveolus could potentially worsen the gas exchange, as well as produce adverse pulmonary mechanics with increased work of breathing. Recent strategies designed to improve edema clearance either using aquaporins or increasing the activity of the Na/K pump could potentially provide a benefit to patients with ARDS. The BALTI trial evaluated the use of intravenous β -agonist (salbutamol) in patients with ARDS and demonstrated a significant decrease in extravascular lung water at day 7.¹⁸⁶ The salbutamol-treated group also had lower end-inspiratory plateau pressures, and there was a trend toward a lower Murray Lung Injury Score. This group also had more supraventricular arrhythmias. A subsequent trial by the same investigators (BALTI-2) demonstrated increased 28-day mortality rate (risk ratio 1.47) with the use of intravenous salbutamol (albuterol).¹⁸⁷ The NHLBI ARDS Network investigators evaluated the use of nebulized salbutamol (albuterol 5 mg every 4 hours) and reported no change in ventilator-free days nor in in-hospital mortality rate.¹⁸⁸ The amount of edema in the lung can also be increased when there is a low oncotic pressure. To evaluate the potential benefit of infusing albumin and furosemide as opposed to furosemide alone to patients with ARDS, Martin and colleagues¹⁹⁰ conducted a randomized controlled trial in 40 hypoproteinemic patients with ALI. The albumin-infused group had an improvement in oxygenation, total protein, net fluid loss, increased number of shock-free days, and less hypotension. Although this is a small study, it does suggest a potential benefit of this maneuver in hypoproteinemic ARDS patients. Further investigation is necessary to determine the benefit of edema clearance strategies in the management of ARDS patients.

EXPERIMENTAL/INNOVATIVE THERAPIES

In an attempt to reduce the high mortality rate associated with ARDS, a number of experimental and innovative therapeutic approaches have been evaluated. A majority of these approaches target abnormalities that either produce or result from the systemic inflammatory response that is felt to be central to the pathogenesis of the injury. To date, none of these approaches has been demonstrated to offer significant benefit in well-conducted, prospective, randomized controlled, multicentered clinical trials. These approaches have included the early administration of high-dose corticosteroids, prostaglandin E₁, nonsteroidal anti-inflammatory drugs, antiendotoxin and anticytokine therapy, inhaled nitric oxide, surfactant therapy, antioxidant therapy, positional changes, and partial liquid ventilation.^{169-174,177,185,191,192,198-234}

Many investigations in experimental animal models of ARDS have demonstrated benefit from pretreatment and early treatment with high-dose corticosteroids.¹⁹⁸⁻²⁰¹ Similar benefit has been observed with a number of nonsteroidal anti-inflammatory agents in experimental animal models of lung injury.^{202,210,211,235} Unfortunately, the use of anti-inflammatory strategies in humans with sepsis or ARDS has repeatedly failed to demonstrate significant benefit.^{195,203,205,206,236,237} In fact, in subgroup analysis there was evidence of potential harm in patients with renal dysfunction who were administered high-dose methylprednisolone for treatment of severe sepsis and septic shock.²⁰⁶ To further complicate this clinical situation, it has been demonstrated that a significant proportion of patients with septic shock and other critical illnesses have relative adrenal insufficiency as defined by the inability to elevate the plasma cortisol level more than 9 $\mu\text{g/dL}$ after adrenocorticotrophic hormone (ACTH) stimulation.²³⁷ This relative adrenocortical deficiency has been implicated as a potential cause of the persistent shock state and impaired perfusion. However, these patients have not always been responsive to the administration of steroids, and the adrenergic hyporesponsiveness may be related to sepsis-induced nitric oxide production, desensitization, or downregulation of α - and β -adrenergic receptors.²³⁷ Lower-dose, more physiologic steroid replacement may restore the α - and β -adrenergic responsiveness and potentially turn off the inflammatory reaction to allow for better healing and less injury.²³⁷⁻²³⁹ Attempts to prevent the development of ARDS in high-risk patients with severe sepsis and septic shock with high-dose corticosteroids have not been shown to prevent the development of ARDS, improve the reversal of ARDS, or improve the outcome from ARDS.²⁰⁶

Steroid therapy has been shown to be beneficial in patients with severe *Pneumocystis jiroveci* (*carinii*) pneumonia and ARDS and possibly in patients with fat embolism.¹⁹⁸ In the patient with adrenal insufficiency, stress dose steroids should be administered. The use of corticosteroids to treat patients with established ARDS is controversial and is discussed later. Ibuprofen, a nonsteroidal anti-inflammatory drug, failed to significantly improve the outcome of patients with severe sepsis or septic shock and failed to prevent the development of ARDS in a prospective, randomized, placebo-controlled, multicentered clinical trial.²³⁶

A plethora of clinical trials have evaluated “antimediators” that have targeted the potential proinflammatory compounds that can be identified in the blood or BAL of patients at risk for or diagnosed with ARDS.^{8,90,212,240,241} Despite encouraging results from preclinical experimental animal and early clinical studies, these innovative strategies have failed to demonstrate a significant survival benefit.^{8,206,213,216-218,221-229} Attempts to change the inflammatory response by changing the ratio of omega 3/omega 6 fatty acids have evaluated the potential benefit of an enteral nutritional formula rich in eicosapentaenoic acid and γ -linoleic acid.¹⁶¹ A large, multicentered, prospective, randomized trial demonstrated an improvement in lung injury score, oxygenation, and organ dysfunction as compared with an isocaloric, isonitrogenous enteral formulation.¹⁶¹ Unfortunately, a survival benefit was not seen.

Pentoxifylline and lisophylline are xanthine derivatives that were felt to have utility in the management of sepsis and ARDS. Pentoxifylline is a rheologic agent that has the ability to inhibit toxic oxygen radical release, decrease platelet aggregation, decrease phagocytosis, diminish the response to platelet-activating factor (PAF) stimulation, and inhibit the release of tumor necrosis factor (TNF) into the systemic circulation. Clinical evaluation of this treatment strategy by the National Institutes of Health (NIH) ARDS Network found no significant benefit.²⁴⁰

ARDS may be produced or worsened by the elaboration of toxic oxygen radicals from the activated inflammatory cells.⁸ The abundant production of toxic oxygen radicals may overwhelm the ability of the endogenous oxygen radical scavengers, superoxide dismutase (SOD), catalase, and the glutathione redux cycle. The administration of antioxidants such as *N*-acetylcysteine, procysteine, vitamin E, β -carotene, and vitamin C has been evaluated in the prevention and management of patients with ARDS.^{143,233,242,243} No survival benefit was seen associated with the administration of *N*-acetylcysteine or procysteine versus control in patients with ARDS.²³³

PREVENTION

The ability to prevent the development of ARDS would be a welcome achievement that to date has been elusive. Two older trials demonstrated a significant reduction in the development of ARDS in surgical patients when ketoconazole, an imidazole thromboxane A_2 synthetase inhibitor, was administered to an at-risk population of patients.²⁴⁴⁻²⁴⁵ However, when ketoconazole was evaluated by the ARDS Network in the treatment of patients with ARDS there was no benefit on survival.²⁴⁶ The use of 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors (statins) as a prevention for ARDS was evaluated in an observational study of a large cohort of patients at risk for developing ARDS and was not found to decrease the development of ARDS or improve mortality rates, organ failure-free days, or ventilator-free days.²⁴⁷

FIBROPROLIFERATIVE PHASE

An improved understanding of the injury and repair phase of ARDS has resulted in the recognition of the late fibroproliferative phase.^{8,81-84,248} This stage of the injury/repair

process is characterized by replacement of damaged epithelial cells and accumulation of mesenchymal cells and connective tissue products in the airspaces and the intra-acinar microvessels.⁷⁹⁻⁸¹ Clinical manifestations include fever, leukocytosis, diffuse alveolar infiltrates on the chest radiograph, and persistent inflammatory mediators in the serum.⁷⁹⁻⁸¹ Gallium scans demonstrate an increase in pulmonary uptake, and BAL typically contains markers of inflammation and type 3 procollagen peptide.⁷⁹ Physiologic manifestations include the worsening of static pulmonary compliance, abnormal gas exchange, increased dead space ventilation, pulmonary hypertension, and lack of PEEP response.²⁴⁸ This picture of persistent inflammation requires a dedicated approach to ensure that there is not an ongoing uncontrolled infectious process that has not been adequately addressed.²⁴⁸ Once it is determined that this state is not the result of inadequately treated infection, therapy with corticosteroids is used by some experts.²⁴⁸ Several anecdotal reports have suggested that this therapy may have potential efficacy in patients with a persistent inflammatory response.^{198,248} A small, single-center, prospective, randomized, placebo-controlled, double-blind clinical trial in 24 patients with the fibroproliferative phase of ARDS demonstrated an improvement in survival, lung function, and organ system dysfunction.²⁴⁹ This study has been criticized because it included the crossover of patients at day 10 and had a smaller study population than a previously reported uncontrolled trial from the same center.²⁴⁹

The use of steroid rescue for the patient with persistent ARDS or the fibroproliferative phase of ARDS was evaluated by the NIH-sponsored ARDS Network.²⁵⁰ The study prospectively randomized 180 patients with ARDS for greater than or equal to 7 days into a placebo-controlled trial of methylprednisolone versus placebo. The primary efficacy outcome was alive at home at 60 days. Patients with septic shock, a defined need for corticosteroid therapy, disseminated fungal infection, or undrained abscess were excluded. The trial was conducted over 6 years and included a modification of the study protocol that included a reduction in the number of subjects from 400 to 180 and an increase in the inclusion PAO_2/FiO_2 ratio. The use of methylprednisolone was associated with an early improvement in mortality rate, PAO_2/FiO_2 ratio, blood pressure, ventilator, and ICU-free days. An increase in the white blood cell count and glucose level related to steroid administration occurred, along with a decrease in body temperature. No difference was measured in the primary efficacy end point and 60-day mortality rate, and no significant difference in 180-day outcome occurred between the two groups. The steroid treatment was not associated with an increase in serious infections. In fact, there was more pneumonia and septic shock seen in the placebo group than in the steroid-treated group. Unfortunately, the use of steroids was associated with more neuropathy and myopathy, but it is important to note that 30% of the steroid-treated patients were receiving neuromuscular blocking drugs.²⁵⁰ Meduri and colleagues evaluated a low-dose prolonged methylprednisolone infusion in patients with early severe ARDS and noted a significant decrease in lung injury score and C-reactive protein level along with a decrease in ICU mortality rates, duration of mechanical ventilation, and multiple organ dysfunction scores.²⁵¹ The steroid infusion decreased levels of inflammatory

biomarkers and coagulation.²⁵² The prolonged infusion strategy appeared to be safe and well tolerated, but this was a small study of 91 patients and the topic of steroid treatment in ARDS remains controversial; we eagerly await more definitive studies.

Macrolide antibiotics have been said to have important immunomodulatory properties that could prove to be beneficial in patients with ARDS. The ARDS Network has reviewed initial antibiotic data on 235 patients enrolled in the LARMA trial and found that 20% received a macrolide antibiotic within the first 24 hours of the trial.²⁵³ These patients were more likely to have a pulmonary infection as a cause of ARDS. Of interest was the observation that the macrolide-treated patients had a 23% mortality rate compared to 36% mortality rate for nonmacrolide antibiotic regimens.²⁵³ This interesting observation may warrant additional study.

The use of extracorporeal membrane oxygenation (ECMO) was evaluated in the 1970s with dismal outcomes, but with refinements in the ability to provide extracorporeal support in the operative and pediatric settings there has been an increased utilization of the technique in adult patients with severe oxygenation issues related to ARDS.²⁵⁴⁻²⁵⁷ Improved catheters and understanding of the physiology of ECMO has brought the technique into more common use and was found to be associated with lower hospital mortality rate than non-ECMO support in ECMO referred patients with the severe 2009 influenza A (H1N1).²⁵⁷ Significant improvement in outcome was also seen in a report from England, which contrasted treatment at a tertiary care referral center capable of ECMO versus treatment at a center that had only conventional support in patients with severe ARDS.²⁵⁶ Because transfer to a center with ECMO capability did not necessarily lead to institution of ECMO, more stringent study is needed to clearly define the role for ECMO support in patients with significant oxygenation abnormalities associated with severe ARDS.

MULTIPLE ORGAN DYSFUNCTION/FAILURE

A frequent complication of an exaggerated proinflammatory state in the setting of sepsis, SIRS, and ARDS is the development of organ system dysfunction.^{8,18,36,89,258} This dysfunction may involve single or multiple organs.^{160,258} A recent consensus conference has suggested that the dysfunction of two or more organs such that normal homeostasis cannot be maintained in the setting of a systemic inflammatory response to a variety of insults is considered MODS.²⁵⁹ This dysfunction may be partial or complete, reversible or irreversible.¹⁶⁰ A continuum of abnormalities ranging from dysfunction to failure for each organ is probable.¹⁶⁰ Unfortunately, as of this time there has been no consensus on the threshold that separates these two phenomena or the threshold between reversible and irreversible organ system dysfunction.¹⁶⁰

MODS and MOF are the most common causes of death in the noncoronary ICU.^{8,18,258,260,261} Many authorities consider ARDS as the earliest manifestation of an uncompensated systemic inflammatory process with excessive proinflammatory component.^{87,172} One hypothesis for this injury suggests that in the absence of a direct injury to a specific organ, there must be multiple inflammatory insults

to produce the clinically apparent MODS/MOF.¹⁶⁰ This hypothesis, called the “two-hit hypothesis,”¹⁶⁰ suggests that an initial sensitizing insult is followed within a specific period of time by a second insult that is capable of initiating a more profound proinflammatory response because the target cells have been upregulated or primed by the initial insult.¹⁶⁰ Multiple combinations of direct injury, ischemic injury, circulating humoral or inflammatory mediators, translocation of endotoxin or colonic bacteria, altered rheologic properties of the blood cells, or iatrogenic effects of the therapy administered may interact in the eventual production of MODS/MOF.¹⁶⁰

PROGNOSIS

Recent studies report a significant reduction in the mortality rate from ARDS using lung protective ventilatory support and proper levels of PEEP.^{8,83,241,243} Current trials report mortality rates in the range of 30% to 60% in comparison with 60% to 90% of the past.^{8,94,262,263} The 30-day mortality rate seen in patients enrolled in the NIH-sponsored ECMO trial of the 1970s was 91% with both conventional and ECMO treatment.²⁶² Older reports from large tertiary referral centers documented mortality rates of 90% for patients with gram-negative septic shock and ARDS.²⁶³ A large multicenter trial of inhaled surfactant in 725 patients with septic-induced ARDS demonstrated survival rates of 60% at 28 days in both the treatment and the control groups.¹⁷⁶ Today the mortality rate from ARDS appears to depend on the cause of the injury, the patient's underlying disease status, patient age, and institutional factors.^{38,254} This improvement in mortality rate mandates the use of a concomitant control group as opposed to using historical control subjects in the assessment of new innovative therapeutic strategies.

The most common causes of death in patients with ARDS continues to be from MOF and recurrent sepsis.^{3,8,16,36,260,261} Fewer than 20% of patients die because of the inability to adequately oxygenate or ventilate them.²⁶⁰ The complexities of the balance between the proinflammatory and anti-inflammatory processes that encompass the pathophysiologic response of this injury direct the response from organ dysfunction secondary to an overzealous proinflammatory reaction to infectious complications. These complications result from the immune suppression of a predominant anti-inflammatory response.^{83,264} When infection is present, the lung is a frequent site for the process and may be extremely difficult to diagnose.^{35,89,151,152} Patients with pulmonary infections were found to typically have a septic clinical picture without definitive positive culture results.³⁵ On the other hand, in patients who were found to have positive blood cultures without antemortem identification of a specific site, the site of occult infection was commonly found to be in the abdomen at postmortem examination.³⁵ Predictors of high mortality rates from ARDS include the development of multiple organ dysfunction/failure, development of secondary sepsis, concomitant cancer, and the presence of cirrhosis or hepatic dysfunction.¹⁶ A study evaluating predictors of mortality rate in patients with ARDS receiving lung protective ventilatory support reported that the oxygenation index (mean airway pressure \times $\text{FiO}_2 \times 100 \div \text{Pao}_2$) was an independent predictor of mortality rate.²⁶⁵

After recovery from ARDS, the prognosis appears to be reasonably good. A recent report found that 80% of ARDS survivors discharged from the ICU were still alive 5 years later.^{266,267} Although most ARDS survivors have initial abnormalities in pulmonary function quality of life, the majority return to near their baseline pulmonary function status within 3 to 6 months.^{268,269} The major residual abnormality in pulmonary function is a restrictive pulmonary defect and a reduction in the carbon monoxide diffusion capacity.^{268,269} These alterations may result in exercise desaturation in some patients or, more commonly, a decrease in timed walked distance.^{268,269} When observed over the next 5 years, their pulmonary function did not improve a great deal after this initial improvement.^{266,270} However, most patients continue to experience exercise limitation at 5 years, despite the fact that 65% have returned to work.²⁶⁶

Survivors of ARDS have been found to have a decreased health-related quality of life, increased respiratory symptoms, insomnia, depression, anxiety, and posttraumatic stress disorder.²⁷¹⁻²⁷⁴ ARDS survivors have been found to have a clinically significant reduction in their physical function and increased pulmonary symptoms in comparison with the matched survivors of critical illness.²⁷¹⁻²⁷⁷ Survivors of ARDS are also found to have long-term cognitive impairment, problems coping with their disability, and relationship strains.^{274,275} Elderly patients, older than 70 years of age, seem to have worse outcomes with an increase in mortality rate compared with ARDS patients who are younger than 70 years of age.²⁷³

FUTURE CONSIDERATIONS

The growing knowledge of molecular biology and the elaborate mechanisms that govern a person's response to injury, repair, and cell death will likely have a major role in the management of patients with ARDS. Individuals with increased risk for ALI and ARDS development will no doubt be identified on the basis of their genetic profiles. This knowledge will likely affect future management. In years to come, scientists may potentially modify the genetic makeup or the biologic response of a susceptible individual by inserting selected genes or modifying the transcription or function of various regulatory proteins. Studies with mesenchymal stem cells have been conducted in rodents with lung injury and demonstrate potential promise for future therapy.²⁷⁸

SUMMARY

Acute respiratory failure is the inability of the respiratory system to meet the oxygenation (type 1 or hypoxemic failure) or ventilation (type 2 or hypercapnic failure) requirements of the patient. Hypoxemic respiratory failure is defined as a PAO_2 of less than 60 mm Hg and is the result of one of six potential mechanisms: low inspired FiO_2 , hypoventilation, ventilation-perfusion mismatching, shunt, low MvO_2 (pulmonary arterial oxygenation), or diffusion impairment. The exact cause may be elucidated by analysis of the alveolar-arterial oxygen gradient, response to the administration of supplemental oxygen, and the clinical context. Hypercapnic or ventilatory failure is defined as a

$PACO_2$ of greater than 50 mm Hg, generally with acidemia; it can be acute, chronic, or acute-on-chronic and is the result of one of three potential mechanisms: hypoventilation, increased dead space ventilation, or increased CO_2 production. Clinical manifestations can range from adrenergic sympathetic hyperactivity (tachycardia and hypertension) to tachypnea and respiratory distress to encephalopathy with somnolence. Therapy is with supplemental oxygen, assisted ventilation with or without high levels of PEEP, or both.

ARDS continues to have a significant morbidity and mortality rate despite the advances in understanding and management that have occurred over the past 4 plus decades. Major advances have occurred in our understanding of the pathogenesis and in our ability to adequately provide the required ventilatory support while the injury is allowed to heal. Attention has been directed toward lung protective ventilatory support, the use of local and systemic therapies, and attempts at prevention of injury in high-risk patient populations. Despite recent improvements in management and knowledge of the pathophysiologic alterations likely involved, the mortality rate continues to be unacceptably high. Recent improvements in prognosis have occurred, primarily in those patients younger than age 60. Remembering the systemic nature of the injury and developing effective preventive and reparative strategies is important as we look to the future of ARDS management. Repair of the acutely injured lung, whether from the initial event, the ventilator, or complicating infection, is an important target and may be more achievable than attempting to prevent the initial injury or intervene early enough to prevent the development of ARDS.

KEY POINTS

- Both type 1 and type 2 acute respiratory failure are common problems in the ICU and may represent the primary reason for ICU admission or be a complication arising in the critically ill patient.
- The ABG value is the cornerstone for the diagnosis and management of the patient with acute respiratory failure.
- The American-European Consensus Conference had operationally established definitions that identified a continuum of injury from ALI to the more severe form, ARDS. The degree of oxygenation abnormality distinguished the two. The New Berlin definition suggests that the degree of oxygenation abnormality when assessed on appropriate F_{iO_2} and PEEP has prognostic importance and defines mild, moderate, and severe ARDS with the elimination of ALI as a definitional term.
- The most common clinical risk factors for the development of ARDS include sepsis, SIRS, hypotension, shock, trauma, near-drowning, and aspiration injury.
- The pathophysiology of ARDS represents a complex interrelationship of anti-inflammatory and

Continued on following page

KEY POINTS (Continued)

proinflammatory responses, activation of the coagulation system, abnormal function of the microcirculation, and altered surfactant function. Alterations affect both the capillary endothelium and the epithelial lining cells.

- At this time the management of patients with ARDS is primarily supportive, but it is important to provide specific treatment directed at the underlying predisposing cause, use lung protective ventilation, and prevent complications of critical illness.
- The concept of VILI has now been supported by the results of recent clinical trials demonstrating a survival benefit associated with the use of lower tidal volumes to avoid alveolar overdistention.
- The proper amount of PEEP therapy is important in the management of patients with ARDS to avoid alveolar overdistention and the repetitive collapse and recruitment-derecruitment of alveoli and small airspaces.
- The use of steroids to treat the fibroproliferative phase of ARDS remains a controversial area. If there is no active untreated infectious process and there is a persistent inflammatory process in the lung, there may be a benefit associated with corticosteroid therapy; however, a recent multicenter trial conducted by the ARDS Network did not find a survival benefit at 60 days.
- Although the overall prognosis in ARDS has been improving, there is still a mortality rate that ranges from 30% to 60% and decreased overall health status and function persist for as far out as 5 years after recovery.

COMPLICATIONS OF ASTHMA

APPROACH TO ACUTE LIFE-THREATENING ASTHMA

EPIDEMIOLOGY OF LIFE-THREATENING ASTHMA

In 2010, approximately 25.7 million Americans were diagnosed with asthma, including 7.1 million children. Prevalence of asthma in the United States was about 8.4% in 2010. Prevalence was higher among children, female adults of non-Hispanic black and Puerto Rican race or ethnicity, and those with family income below poverty level. In children prevalence was higher in boys than in girls. Populations at risk for asthma and asthma-related deaths include racial and ethnic minorities. African Americans have been reported to have a greater prevalence of asthma and greater likelihood of dying (190% higher death rate) from asthma compared with whites. The prevalence of asthma attacks is highest among Puerto Ricans.

Worldwide an estimated 300 million people suffer from asthma and this number is estimated to grow by more than 100 million by 2025. About 70% of asthmatics have allergies and 11% of cases are related to workplace conditions such as exposure to fumes, gases, or dust. Older

asthmatic patients (≥ 60 years) tend to have severe or near-fatal asthma exacerbation compared to younger asthmatics (< 60 years).¹⁻⁴

TRIGGERS OF ACUTE ASTHMA

Common triggers for acute asthmatic attacks include air pollutants, respiratory tract infection, and allergen exposure. An association of panic-type anxiety and life-threatening asthma has been suggested. [Box 38.1](#) contains a comprehensive list of precipitating factors.

MORTALITY RATES FOR ASTHMA

In the 1960s, a global alarm was sounded when sharp epidemic increases in asthma death rates were reported. Deaths approximately doubled in the United States from 1980 to 1995. After a long period of steady increase, asthma mortality and morbidity rates have continued to decline for the past decade.^{3,5-7}

Box 38.1 Precipitating Factors for Severe Asthma

Atopy: Genetic factors (inherited predisposition to allergic diseases)
 Environmental factors: Allergens—9% (e.g., dust mites, dogs, cats, cockroaches)
 Upper respiratory tract infection—23%
 Allergic rhinitis
 Pneumonia—9%
 Medications: Aspirin, nonsteroidal anti-inflammatory drugs; β -receptor blockers, angiotensin-converting enzyme inhibitors
 Premenstrual worsening; postmenopausal hormone replacement therapy
 Occupational asthma
 Inhaled irritants (e.g., heroin, cocaine, smoking)
 Reflux esophagitis
 Sinusitis
 Cold: viral infections
 Exercise
 Emotional stress; strong association with panic disorder
 Tapering of steroids—3%
 Noncompliance—32%

Data from references 14-16 and 121-123.

In patients 5 to 44 years old, death from asthma peaks in the summer months, although hospitalizations peak during the winter months. In older asthmatic patients, a different distribution is seen, with hospitalizations and mortality rates both peaking in the winter months. Older patients with asthma also have been shown to have fewer symptoms of dyspnea with methacholine-induced obstruction.⁸

Polynesians, African Americans, and black South Africans all have been reported to have higher asthma mortality rates. Likely reasons include genetic predisposition or poor management of severe asthma attacks because of reduced or delayed use of health care services and lower level of understanding. Self-medication also may play a role. Pendergraft and colleagues⁹ reported that among 29,430 admissions in the United States with a primary diagnosis of asthma, 10.1% were admitted to intensive care units (ICUs), and 2.1% were intubated. The risk of in-hospital death was significantly higher in patients who were intubated and who had comorbid conditions. Near-fatal events occur in 2% to 20% of patients admitted to ICUs with acute severe asthma and in 2% to 4% of those intubated for respiratory failure. Risk factors for death from asthma are previous severe exacerbations with ICU admission or intubation, two or more hospitalizations within the past year, three or more emergency department visits in the past month, use of more than two canisters of short-acting β -agonist in the past month, and difficulty in perceiving or articulating asthma symptoms. African-American ethnicity, low socioeconomic status, urban residence, substance abuse, cigarette-smoke exposure, psychological factors (anxiety and depression), and comorbid problems such as cardiovascular diseases, chronic pulmonary diseases, and chronic psychiatric illnesses are other potential risk factors for death from asthma.

The strongest predictor of mortality risk from asthma is a prior episode of near-fatal asthma, estimated to be 15% to 22%. Asthma death rates per 1000 persons with asthma were 30% higher for females than males, 75% higher for blacks than whites, and seven times higher for adults compared to children. Adults over 65 years old had the highest death rate of 0.58 per 1000 persons with asthma.⁹⁻¹³

CLASSIFICATION

About 5% of asthma patients have “difficult asthma” (asthma difficult to control with maximal recommended doses of inhaled medications, in particular, inhaled corticosteroids). Most of these patients meet the criteria for severe asthma or may have chronic mild or moderate disease with acute exacerbations. Two clinical patterns of life-threatening asthma have been reported. A more serious type is the slow onset of life-threatening asthma characterized by onset over days to weeks, copious amounts of mucoid secretions with intense eosinophilic infiltration, and resistance to bronchodilator therapy. This pattern is described as “slow onset–late arrival,” or type 1, and accounts for 80% to 85% of fatal asthma. Second is the sudden type of asthma characterized by onset over minutes to hours with acute bronchospasm, absence of large quantities of airway secretions with no mucous plugs but neutrophil infiltration of the submucosa, typically a marked response to bronchodilators, and quick recovery in most circumstances. This is described as “sudden asphyxic asthma,” or the type 2 scenario of asthma death. Sudden-type asthma accounts for about 15% to 20% of fatal asthma.¹⁴⁻¹⁶

PATHOPHYSIOLOGY AND IMMUNOLOGY

The pathophysiologic processes leading to pulmonary function abnormalities in severe life-threatening asthma are bronchial smooth muscle contraction, bronchial inflammation–associated mucosal edema, and mucous plugging. Obstruction of airflow leads to low ventilation-perfusion areas and hypoxemia. Expiratory obstruction decreases forced expiratory volume in the first second (FEV₁). The hallmark of asthma is a decreased FEV₁/forced vital capacity (FVC) ratio. A severely asthmatic individual is unable to complete expiration because of expiratory airway resistance and tachypnea-induced limited expiratory time, leading to air trapping and an increasing functional residual capacity and a decreased FVC. The hyperinflation produces increased work of breathing. Edema and increased airway secretions also compromise inspiratory flow and, when combined with hyperinflation, often lead to high peak inspiratory pressures in a patient whose lungs are being mechanically ventilated. The cause of respiratory arrest in asthmatics is usually failure of the inspiratory muscles with ventilatory arrest.

Manthous and Goulding studied the effect of intravascular volume status on deadspace fraction in mechanically ventilated patients with severe asthma. They noted a mean increase in deadspace ventilation of 4.2% in response to intravascular volume expansion with 250 to 500 mL of normal saline solution.^{17,18}

Characteristic findings of fatal asthma are airways showing infiltration with neutrophils and eosinophils, degranulated mast cells, sub-basement membrane thickening, loss of epithelial cell integrity, occlusion of bronchial lumen by mucus, hyperplasia and hypertrophy of bronchial smooth muscle, and hyperplasia of goblet cells. Asthma is an inflammatory response evidenced by the presence of cytokines that mediate inflammation and chemotactic chemokines in bronchoalveolar lavage fluid and pulmonary secretions. Some cytokines initiate inflammatory response by activating transcription factors, which act on genes that encode inflammatory cytokines, chemokines, adhesion molecules, and other proteins that induce and perpetuate inflammation. Adhesion molecules provide a mechanism for the adhesion of inflammatory cells to the endothelium and migration of these cells from the circulation into the lamina propria, epithelium, and the airway lumen itself.¹⁹

Busse and Lemanske described the immunology of allergic inflammation in asthma. IgE antibodies are linked to the severity of asthma. The release of cytokines depends on cross-linking of IgE by allergen. IgE antibodies are synthesized and released by B cells; briefly circulate in the blood; and bind to high-affinity IgE receptors on the surface of mast cells in tissues and peripheral blood basophils and low-affinity IgE receptors on lymphocytes, eosinophils, platelets, and macrophages.²⁰

The early phase of asthma (usually resolves within 1 hour) is characterized by an inhaled allergen precipitating acute constriction of smooth muscles by release of histamines and leukotrienes from mast cells. A prolonged late phase (4 to 6 hours later) occurs as a result of cytokines and chemokines generated by resident inflammatory cells (mast cells, macrophages, epithelial cells) and recruited inflammatory cells (lymphocytes, eosinophils) and causes further obstruction of airflow. Numerous cytokines regulate the function of eosinophils and other cells in asthma. Interferon- γ is elevated in severe asthma during the acute phase. Data also suggest that interferon- γ contributes to the activation of eosinophils and likely augments inflammation. There are two types of helper CD4⁺ T lymphocyte cells. Type 1 helper (T_H1) T cells produce interleukin (IL) 2 and interferon- γ , which are essential for cellular defense mechanisms. Type 2 helper (T_H2) T cells produce cytokines (IL-4, IL-5, IL-6, IL-9, and IL-13) that mediate allergic inflammation. Balance between the T_H1 and T_H2 type cytokine response contributes to the cause and evolution of atopic diseases, including asthma. The increasing prevalence of asthma in Western countries has led to the “hygiene hypothesis.” The immune system in newborns is primarily T_H2 cells, and a timely and appropriate environmental stimulus is needed to create a balanced immune response. Alteration in the number of infections in early life, widespread use of antibiotics, adoption of the Western lifestyle, and repeated exposure to allergens may affect the balance between T_H1-type and T_H2-type cytokine responses and increase the likelihood of immune response by T_H2 cells and lead to asthma. Mild intermittent asthma is thought to be a T_H2 allergen-oriented reaction with adequate apoptosis and self-limiting inflammation, although severe persistent asthma is mediated by T_H1 cytokines with progressive loss of apoptosis leading to longer exacerbations, expanded memory cells, and persistent inflammation. Evidence continues to

underscore the importance of immune factors in the development of asthma and resulting inflammatory process. This particular strategy and insight into the mechanisms of these processes would be important for future treatment of acute severe asthma.^{19,21-25}

Airflow limitation in asthma is caused by bronchoconstriction, airway edema, airway hyperresponsiveness, and airway remodeling. Permanent structural changes can occur with airway remodeling, leading to poor response to therapy, including thickening of sub-basement membrane and subepithelial fibrosis, airway smooth muscle hypertrophy and hyperplasia, blood vessel proliferation and dilation (angiogenesis), and mucus gland hyperplasia and hypersecretion.¹³

ASTHMA GENETICS

Asthma and atopy are complex phenotypes that are influenced by genetic and environmental factors. About 79 genes have been associated with asthma or atopy phenotypes. The *ADAM33* gene has been associated with asthma. A locus on the short arm of chromosome 20 has been linked to asthma and bronchial hyperresponsiveness. If further investigations confirm that *ADAM33* is an asthma gene, future studies should enhance understanding of asthma and lead to new therapeutic targets. As Ober and Hoffjan described, such “molecular phenotyping” of patients with asthma and atopic diseases may generate informed decisions regarding treatment, laying the foundation for genomic medicine in the next decade.^{26,27}

SYMPTOMS AND SIGNS

Wheezing may be expiratory and inspiratory and correlates with the degree of obstruction if adequate air movement is present. Absence of wheezing is an ominous finding in a severely distressed asthmatic patient because it implies minimal air movement and is a harbinger of respiratory arrest. Contraction of the sternocleidomastoid muscles and other accessory muscles indicates severe obstruction (FEV₁ < 1 L). Intense inspiratory effort leads to large swings in intrathoracic pressure and to an accentuated pulsus paradoxus (representing a decreased stroke volume during inspiration). Pulsus paradoxus is often appreciated during routine blood pressure measurement in acute severe bronchospasm because systolic blood pressure decreases dramatically during inspiration (this decrease is <10 mm Hg in normal individuals). A decrease of more than 15 mm Hg in a patient in an acute asthma episode is associated with severe reduction in FEV₁.^{18,28,29}

Ominous signs and findings during an acute severe asthma episode include diaphoresis, inability to recline or talk, peak expiratory flow rate (PEFR) less than 60 L/minute, and use of accessory muscles. PEFR less than 25% predicted or personal best is defined as severe life-threatening asthma. In acute severe asthma, lung hyperinflation occurs secondary to increased expiratory airflow resistance, short expiratory time, high ventilatory demands, and increased postinspiratory activity of the inspiratory muscles. The presence of these factors in variable degrees does not allow the respiratory cycle to reach a static

equilibrium volume at the end of expiration. Inspiration begins at a volume in which the respiratory system exhibits a positive elastic recoil pressure called intrinsic positive-end expiratory pressure (iPEEP), or auto-PEEP. This phenomenon is described as dynamic hyperinflation. Dynamic hyperinflation produces a significant decrease in systemic venous return to the heart, leading to a decrease in left ventricular diastolic filling. Also problematic is the increase in left ventricular afterload as a result of large negative intrathoracic pressure swings during inspiration. Pulmonary artery pressure also may be increased secondary to lung hyperinflation, resulting in increased right ventricular afterload. These events combine to produce pulsus paradoxus.¹⁵

Near-fatal asthma presents as raised Paco_2 requiring mechanical ventilation and is associated with high inflation pressures. Life-threatening asthma has any of the following features. Symptoms are altered mental status with confusion or coma, feeble respiratory effort, and exhaustion. Signs are cyanosis, silent chest, hypotension, bradycardia, oxygen saturation below 92% or Pao_2 less than 60 mm Hg, Paco_2 higher than 60 mm Hg, and FEV_1 below 30% predicted or personal best.³⁰

All that wheezes is not asthma. Other entities to consider are upper airway obstruction and “cardiac asthma.” Upper airway obstruction should be considered in patients at risk (e.g., tracheal stenosis in patients who were previously intubated) and when there is no response to therapy in a patient without history of asthma. If the patient’s status would tolerate it, flow volume loops may be diagnostic. Likewise, wheezing that dissipates with intubation should make one suspect upper airway obstruction. Paradoxical vocal cord movement can stimulate asthma. Patients with acute left ventricular failure may wheeze as a result of interstitial fluid compression of bronchioles and edema-associated bronchiolar smooth muscle contraction.^{31,32}

OBJECTIVE MEASUREMENT OF OBSTRUCTION

During an asthmatic attack, all indices of expiratory flow are significantly reduced, including FEV_1 ; FEV_1/FVC ; PEF; maximal expiratory flows at 75% (MEF_{75}), 50% (MEF_{50}), and 25% of vital capacity (MEF_{25}); and maximal expiratory flow between 25% and 75% of the FVC (MEF_{25-75}). With acute asthmatic crisis, high functional residual capacity, total lung capacity, and residual volume are observed.¹⁵

Although spirometry is the best objective measure of airway obstruction, a severely ill asthmatic patient is rarely able to perform the necessary full FVC maneuver. Objective assessment of airway obstruction in a severe asthmatic usually can be made by measuring the PEF because this measurement requires patient cooperation only in the early part of the FVC maneuver. Because the greatest expiratory flow rates exist in early expiration, most patients are able to produce a reliable PEF value. Normal expiratory flow rates vary considerably with age, sex, and height. In adults, a PEF less than 100 to 125 L/minute implies severe obstruction to airflow. A severe exacerbation of asthma is defined as an FEV_1 less than 40% or peak expiratory volume, less

than 40% predicted, or less than 1 L. Values less than 25% are consistent with life-threatening asthma. Failure to improve PEF significantly with initial aggressive bronchodilator therapy is the best predictor of morbidity in a patient with acute severe asthma.¹⁰

LABORATORY AND RADIOGRAPHIC DATA

Asymmetrical breath sounds or chest pain should alert the physician to the possibility of pneumothorax and mandates an early chest radiograph. An increased white blood cell count may be produced by asthma alone in the absence of infection, β -receptor agonists, and theophylline shift of potassium intracellularly. Hypokalemia-induced dysrhythmias could occur after intensive bronchodilator therapy in elderly patients or in patients receiving other therapies that predispose to hypokalemia, such as steroidal and diuretic medications. Creatine phosphokinase (non-MB fraction) may be increased as a result of the strenuous activity of ventilatory muscles. Severe asthma may cause right-sided heart strain as shown on electrocardiogram; this resolves with clinical improvement. Arterial blood gas assessment adds little to the early management of acute asthma. The early stage of asthma usually reveals mild hypoxemia, hypocapnia, and respiratory alkalosis. A non-anion gap acidosis also may be observed in patients with severe asthma if several days of hyperventilation have led to renal compensation with bicarbonate wasting to compensate for the respiratory alkalosis. As the severity of obstruction increases, arterial carbon dioxide (Paco_2) normalizes and then increases as a sign of impending respiratory collapse. After initial therapy, arterial blood gases may be useful for decisions regarding hospital admission or tracheal intubation. Most asthma patients respond dramatically to initial therapy; arterial blood gases obtained when the patient is first seen are rarely predictive of outcome or useful clinically.³³

Early attention should be directed toward aggressive therapeutic intervention. A normal Paco_2 level in a distressed asthmatic patient despite aggressive in-hospital therapy should alert the physician to respiratory fatigue and the danger of respiratory arrest. Respiratory acidosis may be preceded by a lactate-induced anion gap metabolic acidosis. This lactic acidosis is likely caused by a combination of failing inspiratory muscles, aggressive use of β -agonist therapy, and decreased liver perfusion resulting from increased intrathoracic pressure and blood flow diverted to the muscles of respiration. Lactic acidosis occurs more commonly in men and with administration of parenteral β -agonists.³⁴⁻³⁶

In patients with near-fatal asthma, high values for inflammation-related laboratory markers such as erythrocyte sedimentation rate (ESR), C-reactive proteins (CRP), and low nutritional status with low albumin levels were associated with poor prognosis. Exhaled nitric oxide is another biomarker of lung and airway inflammation. Elevated exhaled nitric oxide levels can be found in severe allergic asthma and may predict future exacerbations and steroid treatment response. Use of this biomarker is not recommended at this time and needs further evaluation.^{37,38}

Box 38.2 Conditions Typically Requiring Hospitalization for a Patient with Severe Asthma

Acute respiratory acidosis despite aggressive bronchodilator therapy
 Pneumonia
 Pneumothorax
 Initial PEFR <60 L/min (assumes full cooperation)
 Inability to raise PEFR to 200 L/min despite aggressive therapy
 FEV₁ or PEFR <25% of predicted and fails to improve by >10% after initial treatment
 Inability to boost baseline bronchodilator regimen
 Multiple visits to emergency department for severe asthma attack
 History of tracheal intubation or ICU admission because of asthma

Admission to ICU

Respiratory distress
 High pulsus paradoxus or falling pulsus in a patient with fatigue
 Subjective sense of impending respiratory failure
 Respiratory arrest
 Altered mental status
 SpO₂ 90% despite supplemental oxygen
 Rising PaCO₂ coupled with clinical evidence of nonresolution

FEV₁, forced expiratory volume in the first second; ICU, intensive care unit; PEFR, peak expiratory flow rate.
 Data from references 113 and 115.

INPATIENT ADMISSION DECISIONS

Conditions typically requiring hospitalization for a patient with severe asthma are listed in [Box 38.2](#).

DRUG THERAPY (TABLE 38.1)

OXYGEN

If pulse oximetry confirms the presence of hypoxemia, oxygen should be given to maintain oxygen saturation at greater than 92%. A transient decrease in arterial oxygen tension has been shown in some patients after initiation of β -adrenergic agonist therapy in severe asthma. Mechanisms of this decrease relate to some combination of β_2 -agonist-induced vasodilation in areas of decreased ventilation and increase in pulmonary blood flow resulting from a β_1 -adrenergic inotropic and chronotropic effect. Saturation may decrease initially during bronchodilator therapy with β -agonists, which produce vasodilation and may increase intrapulmonary shunting. Studies in children suggest that aerosolized salbutamol administration may cause hypoxemia during acute episodes of asthma if the drug is administered without oxygen. Most published data show that salbutamol does not have a clinically important effect on oxygenation in asthmatic adults. This seems to be true for stable and acute asthma; however, these studies in adults

exclude the most severe exacerbations more likely to be associated with marked hypoxemia. Because inhaled β -agonist should be given in this circumstance, the only clinical response is to treat any worsening of oxygenation that occurs with additional oxygen. Hyperoxia may be harmful and may be associated with hypercarbia due to regional release of hypoxic pulmonary vasoconstriction during asthma exacerbations.^{5,39-42}

Moloney and colleagues showed that bronchoconstriction induced by dry air challenge can be prevented by humidifying inspired air. Humidification of inspired air should be achieved with a heated cascade humidifier. The use of heat and moisture exchangers is discouraged because they increase the deadspace and add to the expiratory airway resistance.⁴³

β -ADRENERGIC THERAPY

INHALED β_2 -SELECTIVE AGONISTS (ALBUTEROL OR SALBUTAMOL) AND SHORT-ACTING β -AGONISTS

Albuterol is the cornerstone of treatment for acute exacerbation in patients with acute asthma. Initial therapy in an acutely ill asthma patient, as recommended by the National Asthma Education and Prevention Program Update, is 2.5 to 5 mg of albuterol (0.5 to 1 mL of 0.5% solution in 5 mL of normal saline solution) by nebulization every 20 minutes for three doses (for optimal delivery, dilute aerosols to a minimum of 3 mL at gas flow of 6 to 8 L/minute), followed by 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg/hour continuously, with the titration based on response and severity of symptoms. Continuous nebulization should be considered in the most severe patients. Tachycardia and hypokalemia may occur with continuously nebulized albuterol. β_2 -Selective agents delivered parenterally or orally lose much of the β_2 selectivity, which provides the rationale for inhalation treatment as the cornerstone of therapy.^{25,32,39,40,43,44}

Adequate delivery of β -agonists can be accomplished by a metered-dose inhaler (MDI) with spacer during acute bronchospasm if proper technique is used and doses are increased. Four puffs of albuterol (0.36 mg) delivered with a spacer should be expected to be equipotent to 2.5 mg of albuterol by nebulization in patients with severe disease. It is advisable to deliver the β -agonist by nebulization in most acutely ill asthma patients because nebulization requires minimal coordination and cooperation of the patient and less bedside instruction and supervision by health care professionals. Many randomized controlled clinical studies over the last several decades have compared β -agonists delivered by MDIs or by nebulizer. Most studies show similar responses. Protocols typically include methods that ensure proper use of the MDI, however. Greater amounts of drug delivery are required with nebulized therapy to produce the same effect as that seen with an MDI with a spacer. To initiate therapy with nebulized albuterol and then switch to an MDI with spacer after the patient has improved and stabilized may be cost-effective. When aerosol β -agonists are delivered in intubated patients and patients receiving mechanical ventilatory support, much of the physiologic effect is lost as a result of deposition onto the endotracheal tube. Doubling the dose that would be used in a nonintubated patient is recommended.⁴⁵⁻⁴⁷

Table 38.1 Summary of Treatment for Life-Threatening Asthma

Treatment	Dose and Frequency	Comments
Oxygen	1-3 L/min by nasal cannula Goal is to maintain oxygen saturation (SpO ₂) >92% Use heated cascade humidifier to avoid dry air-induced bronchoconstriction	Transient drop in O ₂ tension with β-adrenergic therapy Avoid hyperoxia (may be associated with hypercarbia)
Bronchodilators		
β ₂ -Selective agonists: albuterol or salbutamol, levalbuterol	<i>Albuterol</i> : 2.5-5 mg (0.5-1 mL of 0.5% solution in 5 mL of normal saline) by nebulizer every 20 min for 3 doses total (for optimal delivery, dilute aerosols to a minimum of 3 mL at gas flow of 6-8 L/min), followed by 2.5-10 mg q1-4h as needed, or 10-15 mg/h continuously; titration based on response and severity of symptoms <i>Albuterol MDI</i> , delivered with a spacer (each spacer dose takes 1-2 min; 90 µg/puff), 4-8 puffs every 20 min for 4 h, then q4h as needed <i>Albuterol</i> : 5-7.5 mg by jet nebulizer (each treatment takes 15-20 min) <i>Levalbuterol</i> (0.63 mg/3 mL and 1.25 mg/3 mL nebulizer): 1.25-2.5 mg every 20 min for 3 doses total, then 1.25-5 mg q1-4h as needed, or 5-7.5 mg/h continuous nebulization <i>Levalbuterol MDI</i> (45 µg/puff): 4-8 puffs every 20 min for 4 h, followed by q1-4h as needed	Beta2-selective agonists are the cornerstone of therapy Continuous nebulization used for a majority of severely ill patients In study of continuous vs. intermittent therapy in severe exacerbations (excluding life-threatening asthma), no difference noted in pulmonary function improvement or need for hospitalization Lower frequency of side effects with continuous treatment Watch for hypokalemia, tremors, tachycardia, and lactic acidosis Oral or parenteral route: loss of β ₂ -selectivity MDI: 4 puffs of albuterol (0.36 mg) = 2.5 mg of albuterol nebulization Levalbuterol 0.63 mg = racemic albuterol 1.25 mg for efficacy and side effects <i>Intubated patients</i> : Nebulizers are less efficient in delivering doses to lower airways (6-10%) than MDIs (11%)
Epinephrine	<i>Subcutaneous epinephrine</i> dose for adults: 0.3-0.5 mL of a 1:1000 dilution (1 mg/mL), depending on age and weight; repeat every 20 min for 3 doses total	
Terbutaline	<i>Subcutaneous terbutaline</i> , 0.25 mg; repeat every 20 min for 3 doses total	Terbutaline is the parenteral agent of choice in pregnancy For refractory life-threatening asthma: intravenous epinephrine (high risk for cardiac events, infarction, and arrhythmias) or racemic epinephrine may be considered
Anticholinergics		
Ipratropium (for acute severe asthma warranting visit to emergency department)	<i>Ipratropium bromide</i> : 0.5 mg by nebulizer (0.25 mg/mL) every 20 min for 3 doses, then q2-4h as needed <i>Ipratropium MDI</i> (0.018 mg/puff): 4-8 puffs per treatment every 20 min for up to 3 h <i>Combinations</i> : Albuterol (2.5 mg/3 mL) + ipratropium (0.5 mg/3 mL): 3 mL every 20 min for 3 doses total, then as needed MDI delivering albuterol 90 µg + ipratropium 18 µg: 8 puffs every 20 min for up to 3 h	Ipratropium: Onset of action is slow (20 min), peak effectiveness at 60-90 min, no systemic side effects, improved lung function and reduced recovery time Use a handheld mouthpiece nebulizer (contamination of the ocular area with precipitation of narrow-angle glaucoma may occur if facemask is used for delivery of anticholinergic agent) Ipratropium may be combined with nebulized albuterol dose in the emergency room; no proven benefit shown in hospitalized patients
Corticosteroids: prednisone, prednisolone, methylprednisolone	40-80 mg/day in 1 or 2 divided doses until peak expiratory flow reaches 70% of predicted or personal best FEV ₁ or PEFR <50% ¹⁶ Methylprednisolone 40 mg IV q6h OR Hydrocortisone 200 mg IV	No advantage of higher doses No advantage of IV therapy over oral if absorption and gut transit are not impaired Total steroid course: 3-10 days, <1 week; no need to taper steroids Inhaled steroids can be started at any time

Table 38.1 Summary of Treatment for Life-Threatening Asthma (Continued)

Treatment	Dose and Frequency	Comments
Heliox	Helium-oxygen mixture (80-20 or 70-30) Routine use cannot be recommended at this time	Improves O ₂ and aerosolized medication delivery to distal lung Decreases flow turbulence and resistance Lower gas density facilitates exhalation, reduces air trapping and intrinsic PEEP Improves pulmonary function in subgroup of patients with most severe airflow obstruction
Magnesium sulfate	2 g IV given over 20 min; may repeat Monitor magnesium levels Avoid in renal insufficiency	Bronchodilatation from inhibition of the calcium channel and decreased acetylcholine release IV and inhaled or nebulized magnesium sulfate improves pulmonary function in acute severe asthma IV magnesium widely used as adjunct therapy

FEV₁, forced expiratory flow in 1 second; MDI, metered-dose inhaler; PEF, peak expiratory flow rate.
Data from references 13, 16, 52, 111-115.

Aggressive inhaled selective β_2 -agonist therapy is preferred to intravenous albuterol because the same end point usually can be achieved with less risk for toxicity. Intravenous albuterol (if available) may be considered as an alternative when patients with life-threatening asthma have failed to respond to inhaled therapy. Oral β_2 -selective agents should not be used as primary treatment for patients with acute asthma because the therapeutic-to-toxicity ratio is less than with inhaled agents. Effects of corticosteroids and β_2 -agonists on airflow obstruction may be additive.⁴⁸

Levalbuterol, 0.63 mg, is equivalent to racemic albuterol, 1.25 mg, for efficacy and side effects. Levalbuterol is available as 0.63 mg/3 mL and 1.25 mg/3 mL nebulizer solutions. The recommended adult dose of levalbuterol is 1.25 to 2.5 mg every 20 minutes for three doses, then 1.25 to 5 mg every 1 to 4 hours as needed, or 5 to 7.5 mg/hour continuous nebulization.²⁵

In outpatient settings, monotherapy with inhaled long-acting β -agonists (LABA, salmeterol, Formoterol) has been shown to increase severe and life-threatening asthma exacerbations and asthma-related deaths.³⁰

SUBCUTANEOUS β -AGONIST THERAPY (EPINEPHRINE OR TERBUTALINE)

Subcutaneous β -agonist therapy has a disadvantageous therapeutic-to-toxicity ratio compared with inhaled β_2 -selective agonists. Although there is no proven value of systemic therapy over aerosol therapy, rapid delivery of β -agonists to the airway may be beneficial in seriously ill asthmatic patients who are at imminent risk for respiratory arrest or in need of intubation and at low risk for β -agonist cardiac toxicity (young asthmatics). In this circumstance, a combination of inhaled and subcutaneously administered β -agonists may be useful. The subcutaneous epinephrine dose for adults is 0.3 to 0.5 mL of a 1:1000 dilution (1 mg/mL), depending on age and weight; it may be repeated in the initial management every 20 minutes

for three times. An alternative subcutaneous β -agonist agent is subcutaneous terbutaline, 0.25 mg, which can be repeated every 20 minutes for three doses. When subcutaneous terbutaline is compared with subcutaneous epinephrine, equal cardiac side effects are seen. No clinical studies document benefit of subcutaneous terbutaline over subcutaneous epinephrine. Terbutaline is, however, the parenteral agent of choice in pregnancy. β_1 -Adrenergic stimulators are given subcutaneously with caution to the elderly and to patients with documented or suspected coronary artery disease.^{49,50}

Anecdotal reports have suggested the success of epinephrine administration through the endotracheal tube after respiratory arrest from asthma. Prospective trials are needed in this area. Despite the lack of confirmatory studies, in an asthma patient with respiratory arrest, it may be considered.⁵¹

CORTICOSTEROIDS

Corticosteroids are an essential part of in-hospital asthma therapy. The National Institutes of Health expert panel recommendation is intravenous methylprednisolone, 40 to 80 mg/day in one or two divided doses, until PEF reaches 70% of predicted or personal best. This is substantially lower dosage than the previous recommendations. Initial high-dose steroids with intravenous methylprednisolone 80 to 125 mg/day in divided doses (typically 40 mg every 6 hours) for the first 24 hours was recommended if the PEF or FEV₁ remains less than 50% in severe asthmatics.¹⁶ In hospitalized patients the use of higher than standard doses of prednisone (40-80 mg/day) offers no benefit. No differences in clinical effects between oral and intravenous forms of corticosteroid therapy have been proved. In acute severe asthma, intravenous steroids offer benefit with the possibility of early onset of action and peak effect. Some trials show improvement following initiation of steroids after a patient's condition was refractory to initial therapy. Others show benefit

Box 38.3 Potential Benefits of Corticosteroids in the Treatment of Asthma

Enhancement of β_2 -receptor responsiveness by upregulating β_2 -receptors on airway smooth muscle
 Decrease in capillary basement membrane permeability; decrease vascular leak from endothelial cells
 Decreased leukocyte attachment; decreased number of eosinophils, mast cells, and dendritic cells
 Modulation of calcium migration intracellularly
 Reduction in airway mucus production
 Suppression of IgE receptor binding
 Interruption of arachidonic acid inflammatory pathways
 Decreased airway smooth muscle contraction, mucosal edema, and airway inflammation
 Airway remodeling
 Decreased cytokine and mediator production from epithelial cells

Data from references 13 and 52.

when corticosteroid therapy is initiated early in the course of an acute asthma episode. Most corticosteroid benefit is thought to be delayed for approximately 6 hours, although a potential for earlier beneficial effect has been postulated. The delay in effect may reflect the time necessary for steroids to induce upregulation of new β_2 -receptors and reversal of β_2 -receptor desensitization and downregulation. Some patients show corticosteroid resistance. Inhaled corticosteroids can be started any time during the exacerbation. Total course of steroids can be 3 to 10 days and less than 1 week; there is no need to taper the dose.^{13,16,52} Potential benefits of corticosteroids are listed in Box 38.3.

INHALED ANTICHOLINERGIC THERAPY WITH IPRATROPIUM

Although ipratropium achieves less bronchodilation at peak effect than β -agonists and less predictable clinical response, the effect is likely to be additive to albuterol. Most published evidence supports the addition of ipratropium to inhaled β -agonist therapy for acute asthma patients. It produces clinically modest improvement in lung function compared with albuterol alone. Addition of multiple high doses of ipratropium bromide in acute severe airflow obstruction in asthma patients in the emergency room has resulted in fewer hospital admissions. After admission to the hospital for acute severe asthma, clinical benefit from the addition of ipratropium is not detected in trials.^{13,42,53,54}

The National Institutes of Health expert panel's recommended dose of ipratropium is 0.5 mg by nebulizer every 20 minutes for three doses, then every 2 to 4 hours as needed. Onset of action is slow (20 minutes), with peak effectiveness at 60 to 90 minutes and no systemic side effects. A handheld mouthpiece nebulizer system should be used for nebulization because contamination of the ocular area with precipitation of narrow-angle glaucoma may occur in susceptible individuals if a facemask is used for delivery of an anticholinergic agent. Ipratropium may be combined

with the nebulized albuterol dose. The deposition of ipratropium may be enhanced, however, when it follows albuterol-induced bronchodilation. In a patient with severe asthma, ipratropium may produce a clinically significant response within minutes of administration, as opposed to the longer delay to response in chronic obstructive pulmonary disease patients with chronic stable disease. If ipratropium is delivered by MDI (0.018 mg/puff), 4 to 8 puffs per treatment is recommended.^{13,40}

METHYXANTHINES: THEOPHYLLINE OR AMINOPHYLLINE

Although theophylline or aminophylline is an effective bronchodilator compared with placebo in patients with acute bronchospasm, inhaled β -agonists are accepted to be superior to theophylline as single agents for acute bronchospasm. Consensus opinion and meta-analyses support no significant additive clinical benefit with the addition of theophylline to a full course of inhaled β -agonists. Although a few studies have shown physiologic benefits evident at 24 or 48 hours, the addition of theophylline to high-dose inhaled β -agonist and corticosteroid therapy in patients with acute severe asthma seems to offer no clear-cut or substantial clinical benefit. Methylxanthines are infrequently used for acute asthma because of unpredictable pharmacokinetics and known side effects.^{40,55-58} Because theophylline toxicity is a potential problem, the use of theophylline should be limited to patients with life-threatening asthma who fail to respond to other therapy.

MAGNESIUM SULFATE

Magnesium has multifactorial actions relative to potential reversal of bronchoconstriction, which is based on characteristics of inhibition of the calcium channel and decreased acetylcholine release. Hashimoto and colleagues⁵⁹ showed that 40% of asthmatic patients exhibited magnesium deficiency, and that low magnesium erythrocyte concentrations reflected decreased magnesium stores in patients with bronchial asthma.

A Cochrane meta-analysis concluded that use of intravenous magnesium sulfate improves pulmonary function and decreases hospital admissions in acute severe asthma, particularly in patients with severe exacerbations. Inhaled magnesium sulfate improves pulmonary function during acute exacerbations of asthma, although it fails to show alterations in clinically important outcomes, such as hospital admissions. Magnesium sulfate can improve pulmonary function modestly and when dosed appropriately has no significant side effect profile.

Traditionally, 2 g of magnesium sulfate is administered over 20 minutes. Repeat doses, if used, require careful monitoring of magnesium levels and assessment for clinical manifestations of toxicity. Magnesium therapy should be avoided in the presence of renal insufficiency.⁵⁹⁻⁶¹

HELIOX

Heliox (mixture of helium and oxygen optimally effective at a 70:30 mix) has been shown to improve the delivery and deposition of nebulized albuterol. If a patient requires more

than 30% oxygen, it cannot be used. Heliox may be useful in acute severe asthma refractory to conventional treatment. There are no data to support the use of heliox as the initial treatment for acute severe asthma. Heliox is available in mixtures of 60:40, 70:30, and 80:20. Helium is less dense than air and can be delivered through a tight-fitting nonrebreathing mask or, in an intubated patient, through the ventilatory circuit. Heliox results in decreased large airway resistance. One might anticipate that the role of heliox would be limited by the fact that heliox improves flow in large turbulent airways, and most of the obstruction in asthma is in the peripheral airways. Studies have nonetheless shown the ability of heliox to decrease inspiratory and expiratory resistance in severe asthma. Its potential to decrease PEEP not set on the ventilator (auto-PEEP) might be particularly useful. Heliox may augment carbon dioxide removal by facilitating carbon dioxide movement across the endothelial-epithelial barrier compared with the presence of a mixture of oxygen and nitrogen as the carrier gas. Heliox also has been shown to improve oxygenation, which may allow higher helium concentrations to be delivered.⁶²⁻⁶⁴

OTHER AGENTS

ANTIBIOTICS

Antibiotic therapy in an asthma patient is indicated only if bacterial infection is present. The Telithromycin, Chlamydia, and Asthma (TELECAST) study reported that, in patients presenting for unscheduled care because of an acute asthma exacerbation, treatment with telithromycin showed a significant improvement in FEV₁ over placebo at the end of a 10-day treatment period.⁶⁵ One of the primary efficacy end points, improvement in asthma symptom scores, was significantly greater in the telithromycin group than placebo. An editorial pointed out the possible anti-inflammatory effects of macrolides in the treatment of asthma but did not recommend this as standard therapy at this time.⁶⁶

FLUIDS

If the patient is volume depleted, normal saline or lactated Ringer's solution is used to reestablish adequate intravenous volume. There is no evidence that excess volume replacement liquefies or facilitates loosening of secretions. Chest physiotherapy and other maneuvers to mobilize secretions physically also are not recommended. Nebulization of acetylcysteine is not indicated and may irritate the airways. Saline solution and acetylcysteine have been successfully used as part of bronchial lavage with fiberoptic bronchoscopy in patients with severe asthma.⁶⁷

KETAMINE

Ketamine is an intravenous analgesic agent that has bronchodilator properties but may stimulate bronchial secretions and laryngospasm and may cause tachycardia, hypertension, delirium, dissociative state, and lowering of seizure threshold. So far no trials have been published to prove its effectiveness. When intubation of a severe acute asthmatic is required, in the absence of hypertension and known seizure disorder, ketamine seems to be an optimal induction agent. It also may be used in life-threatening situations when conventional therapy has failed.^{40,68}

LEUKOTRIENE ANTAGONISTS

Leukotriene receptor antagonists (LTRAs: montelukast, zafirlukast) improve lung function and are often used in the management of chronic asthma, but their role in acute asthma is unclear. Significant improvement in pulmonary function within 10 minutes of intravenous administration of leukotriene antagonists was demonstrated in one study in patients with severe asthma exacerbation.⁶⁹

OMALIZUMAB (ANTI-IGE ANTIBODY)

Recombinant anti-IgE antibody (omalizumab) improves asthma control in severely allergic asthmatics, reducing inhaled steroids and rescue medication requirement and improving asthma-related quality of life. Its role in acute severe asthma is unstudied. The delay in onset of effect likely makes its impact less likely.⁷⁰

Strunk and Bloomberg reported that patients likely to benefit from omalizumab are patients with evidence of sensitization to perennial aeroallergens who require high doses of inhaled corticosteroids that have a potential for adverse effects, patients with frequent exacerbations of asthma, and patients with severe disease-related noncompliance. Total IgE levels should be measured in all patients, and the recommended dose, 0.016 mg/kg body weight per international unit of IgE every 4 weeks, should be administered subcutaneously at 2- or 4-week intervals. Strunk and Bloomberg recommended adding omalizumab in a compliant patient with severe asthma after a trial of leukotriene modifiers or extended-release theophylline proved ineffective.⁷¹

NONTRADITIONAL THERAPY OF SEVERE BRONCHOSPASM (TABLE 38.2)

Asthmatic patients who fail to respond to conventional therapy should be considered for nontraditional therapy. Nontraditional treatment alternatives include intensification of β -agonist therapy beyond routinely recognized standards, general anesthetic agents, and bronchial lavage. Continuous intravenous albuterol has been used in Europe but is unavailable in the United States. It is unlikely that it adds any additional benefit over increasing the aggressiveness of treatment with inhaled bronchodilators. Intravenous isoproterenol and terbutaline have been used in children but are not recommended in adults.

In a patient with refractory severe asthma who is receiving mechanical ventilatory support, anecdotal success with isoflurane or halothane anesthesia, intravenous thiopental, and rectally administered ether has been reported. Intravenous ketamine has the potential for administration in the ICU and is likely the best alternative for anesthetic therapy. Que and Lusaya anecdotally showed significant improvement when using sevoflurane induction for emergency cesarean section in a woman with severe life-threatening asthma. Maternal and neonatal outcome were good. Propofol has been reported to relax smooth muscle in arteries and veins, and a bronchodilator effect has been suggested. A case series report showed temporally related improvement in severe asthmatic bronchospasm after propofol infusion.⁷²⁻⁸⁰

Table 38.2 Adjunct Therapies for Bronchospasm

Nontraditional Therapy for Severe Bronchospasm	Comments
Intravenous β_2 -agonists	No data show any benefit in adding IV agent to nebulization Avoid IV isoproterenol owing to danger of myocardial toxicity
Oral or IV leukotriene receptor antagonists (LTRAs): montelukast 10 mg oral daily, zafirlukast	Rapid bronchodilation in impending respiratory failure Improves pulmonary function within 10 min Oral LTRAs can be added as an adjunct in severe asthma
Non-invasive positive-pressure ventilation (NPPV)	NPPV reduces the need for endotracheal intubation in severe asthma exacerbation
Inhaled nitric oxide (NO) (adding 15 ppm to the inspiratory circuit)	Rapid improvement in ventilated patients with asthma refractory to medical treatment
Omalizumab (anti-IgE antibody)	Role in acute asthma is unstudied Improves asthma control in allergic asthmatics
General anesthetic agents: isoflurane or halothane anesthesia IV thiopental, IV propofol, IV ketamine	Propofol relaxes the smooth muscles in arteries and veins and has bronchodilator effect
Plasma exchange (during pregnancy)	Case reports of adjunct therapies; used as salvage therapy for life-threatening asthma
Pumpless extracorporeal carbon dioxide removal	
Extracorporeal life support (ECLS)	
Glucagon	Rapid smooth muscle relaxant, short half-life; small study report
Nebulized DNase (dornase 2.5 mg via tracheal tube)	Case report of use in pregnant patient with rapid improvement
Bronchial lavage	Anecdotal reports: exacerbates auto-PEEP, decreases oxygenation

IgE, immunoglobulin E; IV, intravenous; PEEP, positive end-expiratory pressure.

Data from references 13, 84-86, 116-120.

Although anecdotal success has been reported, critically ill mechanically ventilated asthmatic patients are poor candidates for bronchial lavage because the procedure itself would exacerbate auto-PEEP and decrease oxygenation. The procedure is likely to produce a significant increase in auto-PEEP and worsening of hypoxemia. Anecdotal success has been shown with the use of plasma exchange in refractory life-threatening status asthmaticus in pregnancy. The measurement of preplasma and postplasma exchange complement factors and immunoglobulin revealed 50% elimination. Glucagon, a rapid-acting smooth muscle relaxant with a short half-life, also has been studied for potential benefit in acute severe asthma. In a small study of 21 glucagon-treated (0.03 mg/kg) patients and 25 placebo-treated patients, no differences were found. Successful bronchodilation was defined as a PEFr increase of 60 L/minute at 10 minutes. Standard bronchodilator therapy also was administered. Finally, rapid improvement in a mechanically ventilated asthma patient refractory to medical therapy was temporally related to addition of 15 ppm of inhaled nitric oxide to the inspiratory circuit.

Recent case reports suggest that extracorporeal carbon dioxide removal seems to be a valuable adjunct to mechanical ventilation for life-threatening asthma, and emergency extracorporeal life support (ECLS) as salvage therapy also has been reported.⁸¹⁻⁸⁶

ACUTE SEVERE ASTHMA IN PREGNANCY

Asthma complicates 3% to 12% of pregnancies and is perhaps the most common serious medical problem to complicate pregnancy. Exacerbations occur in approximately 20% of all pregnant women with asthma, can occur any time during gestation, but tend to occur late in the second

trimester. Acute attacks of asthma during labor are rare. Simultaneous management of the mother and the fetus is a challenge. The goal in approaching a pregnant patient with severe asthma is to prevent maternal hypoxemia.^{16,87-89}

Studies of pregnancy-associated asthma reveal increased incidence of maternal and fetal complications, which include preeclampsia, perinatal fatality, low birth weight, and preterm infants. The risk of uncontrolled asthma is considered to outweigh any risk associated with the use of recommended medications for asthma. It is important that a physician skilled in the management of asthma be involved in the patient's care. Uterine contractions are common during asthma exacerbation and usually do not progress to preterm labor. When more than one β -adrenergic tocolytic agent is being administered simultaneously (systemically and inhaled), the possibility of excessive systemic effects should be considered. This is particularly true as it pertains to maternal and fetal tachycardia. One study compared perinatal outcomes in 259 pregnant women treated with inhaled β_2 -adrenergic agonists with 101 pregnant women with asthma not treated with inhaled β_2 -agonists and with 295 pregnant women without asthma and found no difference in rates of perinatal mortality, congenital malformations, preterm delivery, or delivery of low-birth-weight infants. There also were no differences in Apgar scores, rates of complications of labor or delivery, and postpartum bleeding. Oral steroid use was associated with an increased risk of preterm delivery, although it is difficult to separate the effect of the medication from the effect of exacerbation.^{90,91}

Asthma exacerbations have the potential to lead to severe problems for the fetus. During pregnancy, asthma exacerbations should be managed aggressively. During pregnancy, acute severe asthma is treated initially with inhaled short-acting β -agonist by MDI or nebulizer, one to three doses in

the first hour; oxygen; and if no response, oral systemic corticosteroids. If there is severe exacerbation of asthma (PEFR <50%), β -agonist could be given continuously or every 20 minutes, combined with inhaled ipratropium bromide. Fetal assessment and monitoring should be done until the patient is stabilized. To control asthma, there are limited data using leukotriene receptor antagonists in humans during pregnancy, although reassuring animal data are available. Studies and clinical evidence confirm safety of theophylline at recommended doses (to serum concentrations of 5 to 12 $\mu\text{g/mL}$) during pregnancy. There were higher levels of reported side effects and discontinuation of the medication, however. The experimental animal studies confirm the association of high-dose theophylline and adverse pregnancy outcomes in animals.⁸⁷⁻⁹²

MECHANICAL VENTILATION IN ASTHMA PATIENTS

INDICATIONS

Endotracheal intubation should be strongly considered at the time of presentation if the patient has central cyanosis, mental status changes, or a depressed level of consciousness. Inability to oxygenate or ventilate the lungs of an asthmatic patient adequately mandates tracheal intubation. A sustained respiratory rate greater than 40 breaths per minute may imply impending respiratory fatigue and mandates consideration of tracheal intubation. The decision to intubate patients is most frequently made based on clinical deterioration. Patients other than those intubated in association with cardiac arrest had an excellent prognosis.

An increasing arterial Paco_2 despite aggressive therapy is an ominous sign. Although an elevated Paco_2 is not an indication for intubation, an increasing Paco_2 despite aggressive therapy typically calls for intubation and mechanical ventilation. Nowak and colleagues showed that an elevated Paco_2 correlates with FEV_1 less than 25% of age-predicted values. Another sign of imminent respiratory failure is paradoxical breathing. Normally, as the diaphragm contracts, it moves caudad, and the abdomen moves out. When the diaphragm fails, it moves cephalad to fix the rib cage and assist the intercostal muscles of inspiration, and in that circumstance the abdomen moves in with inspiration. The intubation technique should be the one in which the operator feels most proficient. The largest endotracheal tube practical should be selected to decrease the degree of auto-PEEP.⁹³

AEROSOL DELIVERY

Aerosol delivery in an intubated patient receiving mechanical ventilatory support poses a significant problem because the nebulized agent reaching the lung parenchyma is markedly reduced, with most of the agent deposited in the endotracheal tube, probably because of its 90-degree curve. It is important to connect the ventilator circuit nebulizer system as close to the patient as possible and to consider increasing the amount of active agent in each treatment, usually double the dose used in a nonintubated patient. An MDI with a spacer is generally accepted as being as effective in

delivering bronchodilator medication in patients receiving mechanical ventilation as nebulized therapy, and it costs less. Either method may give varying delivery based on technique and ventilator and patient variables.⁴⁸

SEDATION AND ANALGESIA

Sedation and analgesia are almost always required in preparation for intubation in a patient with a severe asthma episode. Sedation and analgesia generally should be avoided in nonintubated patients with asthma unless they are used as part of premedication for intubation. After the patient is intubated successfully and mechanical ventilation has been instituted, a combination of benzodiazepines or propofol and opioids should be administered during initial mechanical ventilator therapy.

NEUROMUSCULAR BLOCKADE

Some patients require neuromuscular blocking agents (NMBAs), especially early in their ventilatory course to control respiratory rate in the presence of life-threatening auto-PEEP and in some patients to facilitate intubation. Status asthmaticus patients receiving mechanical ventilation who are given corticosteroids and NMBAs are at risk for developing prolonged muscle weakness after discontinuation of NMBAs. This is particularly likely in patients with renal impairment, females, associated hypophosphatemia, and higher degrees of paralysis. Concomitant use of corticosteroids and NMBAs typically produces proximal and distal muscle weakness. Creatine kinase may be elevated, and myoglobinuria may be present. Steroid myopathy, by contrast, primarily involves proximal muscles, and the creatine kinase level is normal.⁹⁴

If NMBAs are needed to initially stabilize the intubated, mechanically ventilated asthmatic (oxygenation, ventilation, and blood pressure), intermittent dosing should be used and they should be discontinued as soon as possible. In the rare patient who needs to be continuously paralyzed, infusions must be stopped every 4 to 6 hours to prevent accumulation and evaluation. A peripheral nerve stimulator should be used to limit paralysis to no less than a recording of one or two twitches in response to a train-of-four stimulus, as opposed to higher degrees of paralysis. The rationale for neuromuscular blockade is to control the respiratory rate, decrease chest wall stiffness, eliminate muscle loading from patient-ventilator dysynchrony and oxygen consumption, and lower the risk of barotrauma. These goals can often be achieved with a three-twitch or four-twitch response. If NMBAs are needed for longer than 24 hours, they should be discontinued daily to ensure patient arousal. Prolonged muscle paralysis may lead to a denervated state with an increased number of steroid receptors. The additive effect of NMBAs and steroids may be related to this finding. In patients with asthma, cisatracurium is the first-choice NMBA because it is eliminated by esterase degradation and spontaneous breakdown in the serum.^{16,95-97}

INITIATING MECHANICAL VENTILATION

The strategy of mechanical ventilation is to avoid excessive airway pressures and reduce dynamic hyperinflation. To

achieve this goal, it may be necessary to allow “controlled hypoventilation” or “permissive hypercapnia.” Recommended initial ventilator settings are tidal volume of 8 mL/kg ideal body weight and a frequency of 10 to 14 breaths per minute, minute ventilation less than 10 L/minute, and expiratory time increased and targeted to avoid auto-PEEP and to achieve arterial oxygen saturation greater than 90%. If volume ventilation is used, peak inspiratory flow rates should be set at 60 to 80 L/minute with a decelerating waveform. The use of noncompressible tubing facilitates lowering of inspiratory time and adds to expiration time. Total volume is reduced to 6 mL/kg ideal body weight or less to achieve inspiratory plateau pressure (IPP) of 30 cm H₂O or less. The way to minimize hyperinflation is to minimize inspiratory time (inspiration-expiration ratio $\leq 1:3$) while providing adequate oxygenation and ventilation, considering permissive hypercapnia in the latter case. Controlled mechanical ventilation may be required during initial ICU stay and requires heavy sedation and analgesia, or more typically sedation, analgesia, and muscle paralysis. Assisted controlled ventilation without heavy sedation or sedation/paralysis predisposes the patient to hyperinflation if the patient’s breathing rate is high. Heavy sedation or sedation/paralysis reduces carbon dioxide production, facilitates measurement of end-inspiratory and end-expiratory pressures, and facilitates mechanical ventilation of severely asthmatic patients. Pressure-control ventilation is discouraged because of fluctuating high airway resistance and intrinsic PEEP. Keeping the peak alveolar pressures low (IPP of ≤ 30 cm H₂O) prevents overdistention of alveoli distal to the least obstructed airway.^{98,99}

See [Box 38.4](#) for a summary of general mechanical ventilation guidance in severe asthma with hyperinflation.

AUTO-POSITIVE END-EXPIRATORY PRESSURE

DEFINITION AND PREDISPOSING FACTORS

Auto-PEEP occurs when ventilator settings result in an inspiratory-to-expiratory ratio that does not allow adequate expiratory time for total exhalation of the delivered ventilator breath. Because airway obstruction increases expiratory time, mechanically ventilated asthma patients are at

increased risk for auto-PEEP. After the first breath delivered in a setting conducive to auto-PEEP, the next breath is delivered before complete emptying of the first breath. With each subsequent breath that fails to empty completely, end-inspiratory and end-expiratory lung volumes increase, as do flow and pressure at end expiration. The increase in lung volume predisposes to the risk of barotraumas, and elevations of intrathoracic pressure decrease cardiac output.¹⁰⁰

With volume ventilation, end-inspiratory lung volume and peak alveolar pressure increase until barotrauma occurs, the peak pressure limit alarm setting is exceeded, and total volume decreases, or equilibrium is reached. Equilibrium is established as a result of the distention-induced larger caliber of airways (reduced resistance to expiratory flow) and the increased lung recoil (caused by increased end-inspiratory lung volume), eventually allowing complete emptying of the delivered tidal volume. Equilibrium is reached, however, with significant end-expiratory flow still occurring when the next ventilator breath is delivered.

With pressure-control ventilation, the onset and worsening of acute PEEP decreases delivered tidal volume at the set applied pressure because tidal volume is determined by the ventilator system pressure that is constant and the intrathoracic pressure in the patient, which is increasing. The continued expiratory flow at end expiration represents positive pressure relative to atmospheric pressure. PEEP exists, even though it is not set on the ventilator (auto-PEEP). Auto-PEEP may be associated with significant increases in mean intrathoracic pressure. This condition may be accompanied by associated hypotension (decreased venous return to heart) and barotrauma (pneumothorax).

DIAGNOSIS AND TREATMENT

When there is no other obvious cause (e.g., tension pneumothorax), auto-PEEP should be suspected clinically in an intubated asthmatic patient who is hypotensive after institution of mechanical ventilation. A higher minute ventilation, likely to occur in assist control mode ventilation in an awake asthma patient, predisposes to auto-PEEP. Treatment of auto-PEEP is performed by decreasing total inspiratory time and is best accomplished by decreasing the rate; controlling and minimizing ventilator rate is the most important target of treatment of auto-PEEP. This requires heavy sedation in most cases and NMBAs in some, at least for a short time. Increasing expiratory time is a diagnostic and a therapeutic maneuver and the intervention of choice to treat auto-PEEP. Decreasing tidal volume also is effective but less efficient. Unless inspiratory flow rate was set inappropriately low (<80 L/minute), shortening the total inspiratory time by increasing flow rate is a less effective way of decreasing auto-PEEP and may hyperinflate areas of lung with short time constants for filling. The inspiratory-to-expiratory ratio is not a good barometer for risk for auto-PEEP. Absolute time of expiration for each breath and size of tidal volume are direct correlates of risk for and treatment of auto-PEEP. Auto-PEEP can be detected easily with graphic flow displays showing expiratory gas flow still present at the onset of the next inspiration.

Auto-PEEP can be measured with the occlusion technique or esophageal balloon technique. Occlusion of the expiratory and inspiratory circuit of the ventilator just before the onset of the next breath causes the pressure in

Box 38.4 Mechanical Ventilation Strategies^{99,113}

Goals: To control dynamic hyperinflation: use low tidal volume and respiratory rate (controlled hypoventilation with permissive hypercapnea)

To reduce hyperinflation: use longer expiratory time and lower respiratory rate

F_{IO₂} to maintain saturation $\geq 90\%$

Maintain plateau pressure ≤ 30 cm H₂O

Initiate tidal volume 8 mL/kg and may lower to 6 mL/kg

Initial rate 10 to 12 breaths/min

Inspiratory flow rate 80 to 100 mL/hour

Accept lower than normal pH (permissive hypercapnia) as long as no contraindication (e.g., increased intracranial pressure)

Data from references 99 and 113.

the lungs and ventilator circuit to equilibrate. The displayed pressure represents the level of auto-PEEP. With the esophageal balloon technique, the negative deflection in esophageal pressure (representing pleural pressure) from the onset of inspiratory effort to the onset of inspiratory flow represents both the inspiratory muscle pressure necessary to counterbalance the end-expiratory elastic recoil of the respiratory system and the amount of auto-PEEP. Auto-PEEP (intrinsic positive end-expiratory pressure) is measured as the negative deflection of the esophageal pressure (P_{es}) from the onset of inspiratory effort to the point of zero flow.

In the absence of an esophageal balloon device, the ability to reflect accurately the auto-PEEP-related pressure at the alveolar level in an intubated patient depends on a prolonged end-expiratory hold (3 to 4 seconds) and the absence of patient inspiratory or expiratory effort during measurement. This measurement is unlikely to be accurate unless the patient is heavily sedated or sedated/paralyzed. Unless full equilibration to a no-flow state is allowed at end inspiration with the system closed to the ventilator, the auto-PEEP level exerted at the alveolar level is typically underestimated. The typical end-expiratory hold used in clinical practice of 0.4 to 1 second is less likely to provide a reliable measurement.

INCREASED WORK OF BREATHING WITH AUTO-POSITIVE END-EXPIRATORY PRESSURE

Auto-PEEP in the presence of assisted ventilation modes (assist control and synchronized intermittent mandatory ventilation) implies that the patient must initiate gas flow by producing an inspiratory effort equal to not only the sensitivity setting of inspiratory triggering, but also the level of auto-PEEP. Extrinsic PEEP normally has no indication, however, in acute severe asthma during controlled mechanical ventilation. If it is not advantageous or possible to eliminate auto-PEEP in the patient with assisted ventilation modes, applying or increasing ventilator-set PEEP to a level slightly below total PEEP would decrease patient effort necessary to trigger the ventilator breath. Inappropriately set ventilator PEEP offers additional risks to the patient, and this approach is recommended only by health care professionals well schooled in the intricacies of mechanical ventilation.⁹⁸

BAROTRAUMA

The risk for barotrauma in an intubated asthma patient correlates best with peak alveolar pressure as estimated by IPP. The amounts of measured auto-PEEP and peak inspiratory pressures are less reliable predictors. Peak inspiratory pressure, although correlating to some degree with IPP and end-inspiratory lung volume, also reflects resistance in the endotracheal tube and tracheobronchial tree, which may be considerable in the presence of a small endotracheal tube, airway secretions, mucosal thickening, and bronchoconstriction.

In a heavily sedated or sedated/paralyzed patient, IPP measurement is the best means for estimating peak alveolar pressure and the best indicator of hyperinflation and risk for barotraumas because closure of airways toward the end of expiration may lead to underestimation of hyperinflation. In the presence of normal chest wall and abdominal

compliance factors, an IPP equal to or greater than 30 cm H_2O puts the patient at risk for exceeding maximal alveolar size (total lung capacity). Decreases in IPP are usually accomplished by using low tidal volumes and minimizing auto-PEEP. In a paralyzed patient, the collection of the total exhaled volume of gas obtainable with 20 to 60 seconds of apnea allows the measurement of end-inspired volume above apnea functional residual capacity. This volume may be 3 L despite the use of small tidal volumes.^{101,102}

Because high IPP is reduced by lowering tidal volume, a reduction in the tidal volume directly decreases the risk for barotraumas, as does any maneuver that decreases auto-PEEP. If, after heavy sedation or sedation/paralysis, the IPP remains 30 cm H_2O or greater despite decreases in tidal volume to the lowest value that allows an acceptable pH, typically greater than or equal to 7.20, the use of bicarbonate infusion to allow acceptable pH with further reduction of tidal volume may be considered.¹⁰³

The concept of reducing the tidal volume and accepting a higher $Paco_2$ and lower pH is called *permissive hypercapnia*. Permissive hypercapnia is relatively safe in asthma and well tolerated in the absence of contraindications, such as increased intracranial hypertension and pregnancy. Physicians are uncomfortable with allowing $Paco_2$ to become greater than 80 to 100 mm Hg, but several case reports described short durations of hypercapnia (>150 mm Hg) as well tolerated, and one report described $Paco_2$ of 200 mm Hg for 10 hours with no consequences reported. Permissive hypercapnia limits volutrauma and hemodynamic consequences of increased intrathoracic pressures. In normoxic states, acute hypercapnia has limited potential for inducing severe intracellular acidosis. If permissive hypercapnia results in pH less than 7.2, increased sedation and paralysis and methods of decreasing carbon dioxide production, such as reducing fever, overfeeding, and patient effort, should be considered. In the absence of tissue hypoperfusion or volume overload, iatrogenic compensation for acute respiratory acidosis with intravenous bicarbonate administration is appropriate. In severe acidosis, large amounts of bicarbonate may be necessary to elevate the pH substantially, potentially leading to volume overload.¹⁰⁴⁻¹⁰⁷

Permissive hypercapnia should be considered in the mechanically ventilated asthmatics with life-threatening asthma, severe hyperinflation, and inability to achieve a satisfactory IPP without producing an unacceptable acidemia. Permissive hypercapnia is well tolerated in most patients, even when $Paco_2$ is 90 mm Hg (12 kPa), as long as pH remains greater than or equal to 7.20. It should be avoided, however, in the presence of increased intracranial pressure and clinically significant myocardial dysfunction and during pregnancy to avoid fetal distress.

NON-INVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NPPV) is a safe treatment and can reduce the need for intubation in a selected group of patients with severe asthma and hypercapnia who fail to improve with initial medical management. Fernandez and colleagues further describe that the rationale for NPPV in severe asthma is its potential for improving alveolar ventilation, decreasing the risk of respiratory muscle fatigue. Mask continuous positive airway pressure (CPAP)

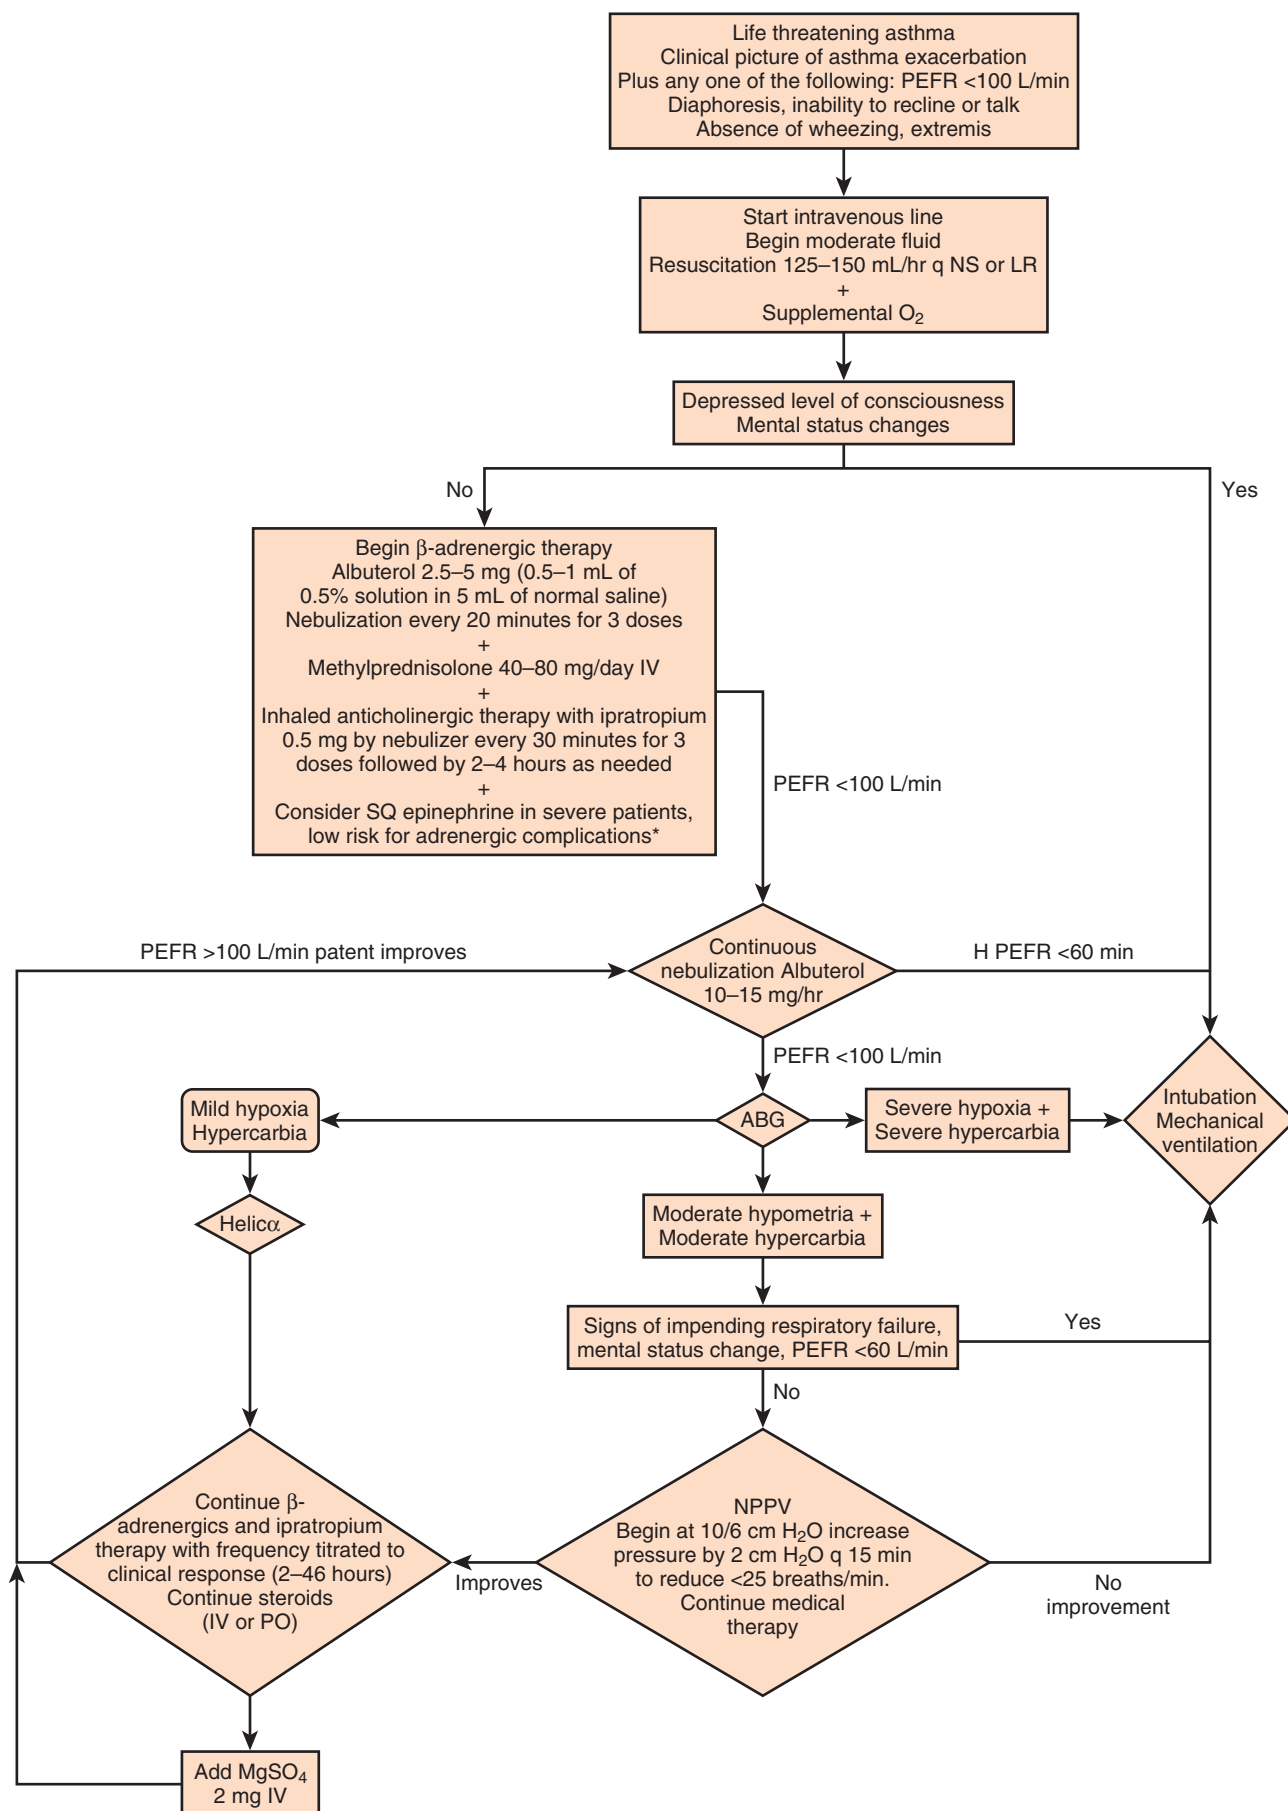

Figure 38.1 Approach to acute life-threatening asthma. *Check for hypokalemia and treat. ABG, arterial blood gas; LR, lactated Ringer's solution; NPPV, non-invasive positive-pressure ventilation; NS, normal saline; PEFR, peak expiratory flow rate.

Box 38.5 Contraindications for Non-invasive Positive-Pressure Ventilation

Uncooperative or obtunded patients
Hemodynamic instability
Cardiac or respiratory arrest
Encephalopathy
Facial surgery or deformity
High risk for aspiration
Nonrespiratory organ failure
Severe upper gastrointestinal bleeding
Unstable arrhythmia
Upper airway obstruction

From Stather DR, Stewart TE: Clinical review: Mechanical ventilation in severe asthma. *Crit Care* 2005;9:581-587.

produces bronchodilation and decreases the airway resistance, reverses atelectasis, and promotes removal of secretions. The work of the diaphragm and the inspiratory muscles is reduced, and intrinsic PEEP may be offset. In addition, CPAP decreases the adverse hemodynamic effects of large negative inspiratory swings in pleural pressure, which compromise right and left ventricular performance. NPPV potentially may enhance delivery of inhaled β -agonists. One study showed a small but statistically significant greater improvement in PEFr when NPPV was used for initial β -agonist delivery. A nonrandomized study by Meduri and associates reported a reduction in PaCO_2 and improvement in dyspnea with the use of NPPV in 17 episodes of asthma with acute respiratory failure.¹⁰⁸⁻¹¹¹

CPAP, as opposed to NPPV, has been studied in asthmatic patients after induction of bronchospasm with aerosolized histamine. CPAP of 12 cm H_2O increased the minimal pleural pressure and decreased swings in transdiaphragmatic pressure. Although ventilation increased, the inspiratory work per liter decreased significantly, as did the pressure time product for the inspiratory muscles. Functional residual capacity increased slightly. The authors concluded that CPAP produced a load on the inspiratory muscles, improving their efficiency and decreasing the energy cost of inspiration. Despite the potential for benefit of NPPV or CPAP in selected patients in severe acute asthma, it should be used with caution pending controlled clinical trials. Ram and colleagues¹¹² also concluded in a Cochrane analysis that application of NPPV in status asthmaticus, despite some promising preliminary results, remains controversial. The need for endotracheal intubation in acute severe asthma has decreased after the introduction of NPPV as shown by a retrospective cohort study. If NPPV is used, initial setting should be an expiratory positive airway pressure (CPAP or PEEP) of about 5 cm H_2O and inspiratory pressure (or pressure support) of approximately 8 cm H_2O . If tidal volumes are shallow (<7 mL/kg), inspiratory pressure can be increased gradually by 2 cm H_2O every 15 minutes, to a goal to reduce the respiratory rate to less than 25 breaths per minute. Peak pressures greater than 15 to 20 cm H_2O rarely can be tolerated without mask leaks or discomfort or claustrophobia.¹⁹ See [Box 38.5](#) for contraindications for NPPV.¹⁰⁸⁻¹¹⁴

Box 38.6 Complications of Acute Severe Asthma

Pneumothorax
Pneumomediastinum
Subcutaneous emphysema
Pneumopericardium
Tracheoesophageal fistula (mechanically ventilated patients)
Myocardial ischemia (coronary artery disease patients)
Mucous plugging and atelectasis
Theophylline toxicity
Lactic acidosis
Electrolyte disturbances—hypokalemia, hypophosphatemia, hypomagnesemia
Myopathy
Anoxic brain injury

COMPLICATIONS OF ASTHMA

See [Box 38.6](#) for complications of asthma.

APPROACH TO ACUTE LIFE-THREATENING ASTHMA

[Figure 38.1](#) is an algorithm that shows the approach to acute life-threatening asthma.

KEY POINTS

- The cause of respiratory arrest in asthmatic patients is usually failure of the inspiratory muscles with ventilatory arrest.
- Ominous signs and findings in a patient with acute severe asthma, if not quickly reversed, include diaphoresis, inability to recline, inability to talk, increased PaCO_2 , PEF less than 60 L/minute or FEV less than 25% of personal best or predicted values, and use of accessory muscles.
- Pathophysiology of asthma consists of three key abnormalities: bronchoconstriction, airway inflammation, and mucous impaction.
- The ADAM33 gene is significantly associated with asthma.
- Inhaled β_2 -agonists are the cornerstone of medical therapy for hospitalized severe asthmatics. The addition of steroids is recommended.
- Adequate delivery of β -agonists can be accomplished by use of an MDI with a spacer during acute bronchospasm if proper technique is used and doses are increased. It is advisable to deliver the β -agonist by nebulization in most acutely ill asthma patients

Continued on following page

Table 38.3 Treatments Not Recommended in Acute Severe Asthma

Intervention/Agent Not Recommended	Comments
Methylxanthines: aminophylline, theophylline	Not recommended in acute severe asthma Use only in patients not responding to standard treatment and refractory Possible treatment adjunct in patients with “steroid-resistant” asthma or those already taking a methylxanthine (Tf)
Antibiotics	Antibiotics indicated only in patients with evidence of pneumonia or sinusitis or fever and purulent sputum
Aggressive hydration	Assess fluid status and appropriate hydration in intubated patients
Chest physical therapy	Not beneficial and stressful to the patient
Mucolytics: acetylcysteine, potassium iodide	May worsen airflow obstruction or cough
Sedation	Avoid anxiolytics and sedatives in nonintubated patients
Long-acting β -agonists: salmeterol, formoterol	No data available on acute severe asthma

From National Heart, Lung, and Blood Institute and National Asthma Education and Prevention Program Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Full report. NIH Publication No. 08-5846. Bethesda, MD, National Institutes of Health, 2007.

KEY POINTS (Continued)

- because nebulization requires minimal coordination and cooperation of the patient and less bedside instruction and supervision by health care professionals.
- Larger doses and more frequent dosing intervals for inhaled β -agonist therapy are needed in acute severe asthma because of decreased deposition at the site of action (low tidal volumes and narrowed airways), alteration in dose-response curve, and altered duration of activity. Continuous nebulization is an option.
 - Theophylline is not recommended for general use in hospitalized patients with acute asthma (Table 38.3). Intravenous magnesium is recommended for the most severe asthma attacks.
 - Although there is no proven value of systemic therapy over aerosol therapy, rapid delivery of β -agonists to the airway may be beneficial in seriously ill asthmatic patients who are at imminent risk for respiratory arrest or need intubation and who are at low risk for β -agonist cardiac toxicity (young asthmatics). In these patients, a combination of inhaled and subcutaneously administered β -agonists in this circumstance may be useful.
 - If NMBAAs are used, attempts to withdraw these agents over the first 24 to 48 hours after intubation are advised.
 - Auto-PEEP is treated by decreasing total inspiratory time. Increasing expiratory time is best accomplished by decreasing rate. Decreasing tidal volume also is effective. Prolonging expiratory time is a diagnostic and a therapeutic maneuver.
 - The concept of reducing the tidal volume to decrease alveolar inflation and accepting a higher PaCO_2 and lower pH is called permissive hypercapnia and should be considered in asthma patients undergoing mechanical ventilation therapy with life-threatening asthma, severe hyperinflation, and high IPP.

PROGNOSIS

TERMINAL CARE FOR THE END-STAGE PATIENT

In 1997, the U.S. National Heart Lung and Blood Institute and the World Health Organization held an international workshop that led to the first Global Initiative on Obstructive Lung Disease (GOLD) report. The most recent iteration of the GOLD guidelines defines chronic obstructive pulmonary disease (COPD) as a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by chronic airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with abnormal inflammatory response of the lungs to noxious particles and gases.¹

DEFINITIONS

Although controversies remain over the definition of exacerbation, how they should be monitored, and their underlying mechanisms, acute exacerbations of COPD (AECOPD) are major and increasingly recognized events in the disease course. They typically occur one to three times per year. Exacerbations are associated with an increase in economic burden² and a decline in health-related quality of life.³ Those patients with more than two exacerbations per year

have significantly worse health-related complications and decline in lung function than those with two or fewer exacerbations.⁴ As mentioned before, there is no general agreement on the definition of AECOPD, but it has been defined according to the presence of specific signs and symptoms, worsening in symptoms, and the need for medical intervention, and each of these approaches has positive and negative connotations. It is well recognized, however, that the presence of increased shortness of breath, increased sputum volume, and increased purulence are the three specific symptoms that represent an exacerbation.⁵

BACKGROUND

COPD affects more than 200 million people worldwide and is the fourth leading cause of death. COPD is a disease that is both preventable and treatable. COPD is a major cause of morbidity and death in the world, with an increasing burden due to epidemiologic changes that expose more of the population to COPD risk factors. Although the major environmental risk for COPD is tobacco smoking, only 20% of smokers develop COPD. Indoor air pollution from burning biomass fuel is associated with increased risk of COPD in developing countries. In the United States, COPD is the

fourth leading cause of death⁶ and is exceeded only by heart attacks, cancer, and stroke.

COPD has had a similar effect on health and mortality rate throughout the developed and underdeveloped sectors of the world, and many of the important issues surrounding COPD in the United States apply elsewhere.⁷

The real prevalence is masked by the burden of undiagnosed COPD; when the British Lung Foundation “missing millions” campaign performed spirometry screening in 3802 adults, they found that the prevalence of COPD was 10.2% (4.4% having GOLD II or worse) with only a quarter having a prior diagnosis.⁸

PATHOPHYSIOLOGY

The main pathophysiologic feature in COPD is the limitation to expiratory flow.⁹ Chronic expiratory flow limitation and hyperinflation are the mechanical hallmarks of COPD.¹⁰ Expiratory airflow limitation results from many factors; among them, narrowing of the peripheral airways,¹¹ mucus hypersecretion,¹² and impaired ciliary clearance¹³ are the most important factors.

Several mechanistic concepts have been implicated in the pathogenesis of COPD. First, the hallmark of COPD is development of exaggerated chronic inflammation in the lung in response to inhalation of cigarette smoke compared with smokers without lung disease.¹⁴ Host factors including genetic susceptibility, epigenetic changes, and oxidative stress contribute by amplifying inflammation induced by cigarette smoke. Second, patients with deficiency of α_1 -antitrypsin, the main inhibitor of neutrophil elastase, develop emphysema early in life owing to an increase in proteolytic activity.¹⁵ Third, an imbalance between oxidants and antioxidants in the lungs of patients with COPD, resulting in excessive oxidative stress, not only amplifies airway inflammation in smokers but also induces cell death of structural cells in the lung. Disruption of the balance between cell death and replenishment of structural cells in the lung contributes to the destruction of alveolar septa, leading to emphysema.¹⁶ Autoimmunity has been proposed as a late pathogenic event in the progressive course of the disease.

COPD is characterized by a specific pattern of inflammation involving increased numbers of CD8⁺ T_C lymphocytes present only in smokers who develop the disease. These cells as well as neutrophils and macrophages release inflammatory mediators and interact with epithelial cells in the airways, lung parenchyma, and pulmonary endothelium; all these relationships and interactions produce structural changes in the lungs by activation of growth factors.¹⁷ Changes in the airway architecture, endothelium, and lung parenchyma lead to the characteristic physiologic abnormalities and symptoms of COPD.

In acute exacerbations there is an increase in sputum neutrophil numbers as well as an increase in neutrophils in bronchial biopsies, which rarely are seen in the stable state.¹⁸ Interestingly virally induced exacerbations are associated with increased expression of eosinophils in sputum. Viral infections induce the expression of chemokine (C-C motif) ligand 5 (CCL5) in airway epithelial cells,¹⁹ CCL5 may act synergistically with CD8⁺ cells to enhance the apoptosis of

virally infected cells, thus leading to increased tissue destruction.²⁰ Also, an increase in the concentration of the elastolytic enzyme matrix metalloproteinase-1 during exacerbations is consistent with evidence of elastolysis, which may provide a causal link between exacerbations and accelerated decline in lung function.²¹

Data from patients with AECOPD that required mechanical ventilation indicates the presence of increased central drive, dyspnea, tachypnea, reduced tidal volume, and development of hypercapnic respiratory failure, but ventilation/perfusion match remains relatively preserved.²² AECOPD appears to be characterized by increased central drive, decreased inspiratory capacity, and decreased inspiratory muscle force, perhaps secondary to dynamic hyperinflation. There is an association between increased serum levels of interleukin 6 (IL-6) and leukotriene B₄ (LTB₄) and the magnitude of dyspnea, respiratory rate, and inspiratory capacity, suggesting that it may be possible to detect serum changes that reflect the inflammatory burden of the exacerbation.²³

Although hypercapnia depends on the severity of airflow limitation, there is considerable variability in the relationship of P_{aCO_2} to forced expiratory volume in 1 second (FEV₁) and total lung resistance, best explained by contribution of dead space and minute ventilation. In stable COPD patients with severe airflow obstruction, shallow breathing is the main factor associated with CO₂ retention,²⁴ the diaphragm is less effective than in normal subjects, and with increasing airflow obstruction and hyperinflation, the contribution of the rib cage muscle to the generation of ventilatory pressure increases.²⁵ Abdominal muscles are recruited during expiration in patients with severe COPD, and the expiratory rise in gastric pressure is directly related to intrinsic positive end-expiratory pressure (PEEP_i). During acute exacerbation, patients with severe airflow obstruction increase the inspiratory recruitment of the rib cage muscles relative to the diaphragm. This recruitment is associated with abdominal muscle contraction and a reduction in abdominal volume at end expiration, which contributes to PEEP_i. Dynamic hyperinflation can be overestimated during chronic and acute airway obstruction if abdominal muscle function is not evaluated.²⁶

The worsening gas exchange and the deterioration of the arterial blood gas values during acute exacerbations in patients with severe COPD can be explained by several factors. These factors are, in no particular order, respiratory muscle fatigue,²⁷ increases in dead space ventilation, and alveolar hypoventilation.²⁸ Minute ventilation may be normal early in an exacerbation, but the respiratory rate is generally increased. There is an associated increase in physiologic dead space that impairs CO₂ elimination and may result in acidemia.²⁹ The hypoxemia seen during exacerbations results from the combination of two factors: alveolar hypoventilation and, later, worsening of ventilation/perfusion matching. Increases in ventilation/perfusion heterogeneity are attributed to (1) a reduction in the effectiveness of hypoxic vasoconstriction as a protective mechanism as pulmonary artery pressure rises and vasodilatory inflammatory mediators are released, and (2) the failure to redirect perfusion away from inadequately ventilated regions because of the reduction in cross-sectional area of the pulmonary vascular bed.

Box 39.1 Clinical Signs of Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Increasing cough
Worsening dyspnea
Increased sputum production
Purulent sputum

CLINICAL MANIFESTATIONS

Most COPD patients with acute exacerbations initially demonstrate some combination of increasing cough, worsening of dyspnea, increased sputum production, purulent sputum, or increase in viscosity of the sputum, rather than a deterioration noted by laboratory or respiratory function parameters (Box 39.1). Symptoms may come on slowly over several days or acutely, depending somewhat on the severity of the underlying disease. Often, patients have a history of upper respiratory tract infection. Patients generally appear in acute distress. Vital signs typically demonstrate tachycardia and tachypnea, and blood pressure can be reduced in response to the effect of PEEPi. Use of accessory inspiratory muscles may be seen with increasing severity of exacerbations. With inspiration, the diaphragm normally moves down as it contracts, forcing the abdominal contents out. With diaphragmatic fatigue, the diaphragm no longer functions as a primary muscle of inspiration but instead assists the intercostal muscles' inspiratory effort by fixing the rib cage. This action is associated with a rise in the diaphragm, and the abdomen moves in instead of out, as it does with normal inspiration. This sign is called *paradoxical breathing*²⁸ and it implies respiratory muscle fatigue and often imminent ventilatory failure and respiratory arrest.²⁹ Wheezing and other auscultatory findings of obstruction are also present. Cyanosis is an insensitive manifestation, but when seen, it denotes severe hypoxemia. Patients with severe acute CO₂ retention may present in coma.

PRECIPITATING FACTORS

The most common precipitant factor is respiratory infection, either bacterial or viral.^{30,31} Air pollution can also precipitate exacerbations of COPD^{32,33}; however, the cause of one third of AECOPD events cannot be identified. Some other conditions that can either mimic or induce an exacerbation include pneumonia, arrhythmia, pneumothorax, pulmonary embolism,³⁴ and pleural effusion. Medication failure and lack of compliance have been shown also to lead to exacerbations.

INFECTIONS

Bacteria and viruses account for the vast majority of episodes of exacerbation. Respiratory viruses are associated with 30% of exacerbations with or without a superimposed bacterial infection.³⁵ Another study reported that up to 78%

of the patients admitted into the hospital with severe AECOPD had evidence of viral or bacterial infection.¹⁹

Several studies have been conducted to investigate airway bacterial infections as etiologic factors involved in COPD exacerbations.³⁶⁻³⁸ Bronchoscopic sampling of the distal airway has demonstrated the presence of pathogenic bacteria in 50% of exacerbations. Acquisition of new strains of bacterial pathogens has been associated with more than twofold increase in the risk of AECOPD.³⁹ At present, there appears to be an agreement that the major pathogens isolated from sputum during acute exacerbation are *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*⁴⁰; however, all of these bacteria can be isolated in patients during the stable phases of COPD.^{41,42} Atypical bacteria, mostly *Chlamydia pneumoniae*, have been implicated in approximately 10% of acute exacerbations.^{43,44} Other potential microorganisms that should be considered include other *Streptococcus* species, enteric gram-negative bacilli, and *Legionella*.⁴⁵ Bacterial colonization may be a factor increasing airway inflammation.⁴⁶ There is an association between bacterial colonization and increased markers of inflammation in sputum and in the frequency of exacerbations.⁴⁷

Approximately 50% of AECOPD events are associated with upper respiratory tract virus infections. Infections with rhinovirus, respiratory syncytial virus, and influenza virus have been associated with AECOPD.⁴⁸ COPD patients with a history of frequent exacerbations may be more susceptible to respiratory viral infections. There is increasing recognition that many patients with exacerbations have concomitant viral and bacterial infection. Approximately a quarter of patients admitted to hospital with AECOPD have coinfection with viruses and bacteria, and those patients have more severe exacerbations.⁴⁸

ENVIRONMENTAL FACTORS

Environmental factors are among noninfectious causes of COPD exacerbation that should be investigated as precipitating causes.^{32,49,50} Epidemiologic studies have shown that hospital admissions with AECOPD increase slightly with a rise in atmospheric levels of sulfur dioxide, ozone, nitrogen dioxide, and particulates. There is convincing evidence that exposure to particulates with a 50% cutoff aerodynamic diameter of 10 µm is associated with increased hospital admissions for AECOPD.⁵¹ Air pollution is implicated as a trigger of exacerbations⁵²; however, a direct cause-and-effect relationship has been difficult to establish over the last 50 years.⁵³ From an epidemiologic viewpoint, definitive evidence exists regarding a role of air pollutants in the increased death rates seen in cities during periods of heavy pollution.⁵⁴ The recent dramatic increase in motor vehicle traffic has produced a relative increase in the levels of newer pollutants, such as ozone and fine-particulate air pollution. Elucidation of the mechanisms of the harmful effects of these pollutants should allow improved risk assessment for the patients with airway diseases who are susceptible to the effects of these air pollutants.

PULMONARY THROMBOEMBOLISM

Pulmonary thromboembolism (PTE) can precipitate acute COPD exacerbations through either impairment of gas

exchange or increases in pulmonary vascular pressures.^{55,56} Some evidence suggests that deep venous thrombosis occurs in more than 5 million people each year. More than 500,000 people eventually develop PTE, which is the primary cause of death in more than 100,000 patients annually in the United States.⁵⁷ The precise incidence of PTE in COPD is unknown. Studies in COPD patients have found pulmonary embolus in up to 50% of autopsies and in patients admitted to hospital with severe AECOPD of unknown cause; 25% had pulmonary embolism confirmed by spiral computed tomography (CT).⁵⁸ PTE risk factors inherent to COPD are sedentary lifestyle, right ventricular failure, right ventricular mural thrombi, and secondary polycythemia.⁵⁹ Patients with COPD have also been shown to have increased platelet aggregation and increased plasma β -thromboglobulin.⁶⁰

Up to 30% of untreated thromboembolic patients die. The necessity of diagnosing PTE as the precipitating factor in acute COPD exacerbation is crucial. However, the diagnosis of PTE is extremely difficult in COPD exacerbation. Nonetheless, the approach to diagnosis is similar to that used with other patients.⁶¹ Unfortunately, most patients with COPD have an indeterminate ventilation/perfusion scan, usually making this scan unhelpful in evaluation for PTE.⁶² For patients with such indeterminate results (low or intermediate probability), noninvasive testing of the lower extremity should be conducted.⁶³⁻⁶⁵ If positive results for deep venous thrombosis are obtained, anticoagulation therapy must be initiated. It has been proposed that use of newer D-dimer assays may also have a role as a diagnostic tool; however, even with a sensitivity of 98%, specificity is problematic, with a value of 39%.⁶⁶ When the diagnosis is still in doubt (intermediate-probability scan and negative leg study or low-probability scan and negative leg study with intermediate clinical probability of PTE), helical CT or conventional pulmonary angiography may be required. Even though the safety of pulmonary angiography in patients with cor pulmonale has been questioned, data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study support both safety and accuracy in patients with COPD.⁶¹ Helical CT has become an increasingly accepted technique and is the method of choice for direct visualization of pulmonary emboli (PE). The quantitative assessment of tissue perfusion may yield more important information for patient management than the direct visualization of emboli by CT alone. Enhanced multislice helical CT with thin collimation can be used to analyze precisely the subsegmental pulmonary arteries and may identify even more distal pulmonary arteries. Recent data suggest that spiral CT may be an alternative to angiography, particularly when results are not discordant with pretest clinical probability of PE and when combined with other tests that support CT findings (D-dimer, leg ultrasound, lung scanning), and may have adequate sensitivity and specificity in the COPD population.⁶²

MEDICATION FAILURE OR NONCOMPLIANCE

Many acute COPD exacerbations can be explained in terms of inadequate pharmacologic therapy or noncompliance with pharmacologic therapy. These factors are likely underestimated causes of exacerbation in COPD patients. It is also possible that patients have toxic drug effects of cardiac,

gastrointestinal, or metabolic nature. Certain pharmacologic drug interactions can precipitate toxicity or loss of effect of one drug, and the physician must ascertain whether newer medications for other conditions have recently been added to the patient's therapeutic regimen.^{67,68}

OTHER CAUSES

Clinical decompensation in patients with stable COPD may also occur as a result of acute congestive heart failure (CHF) or cardiac arrhythmia. One study found that 27% of COPD patients die as a result of coronary disease,⁶⁹ likely related to risk factors such as smoking, diabetes mellitus, and vasculopathy. Heart failure may also lead to a symptomatic exacerbation of COPD; however, it may be difficult to differentiate the symptoms of CHF and those of AECOPD.⁷⁰

Other causes of exacerbation include sleep-disordered breathing,⁷¹⁻⁷³ vocal cord paralysis, tumor or scarring from prior intubations, and the development of spontaneous pneumothorax.^{74,75} Finally, pleural effusion can also produce respiratory deterioration, especially in patients with poor respiratory reserve.⁷⁶

INITIAL MANAGEMENT

Because chronic airflow obstruction cannot be reversed, acute management of COPD is directed at reversible pathogenic mechanisms, including pulmonary infection, airway tissue inflammation, bronchoconstriction, and support of failing muscular function. **Box 39.2** summarizes initial general management.

OXYGEN

Long-term oxygen treatment has been demonstrated to significantly reduce mortality rate in patients with COPD and severe resting arterial hypoxemia.⁷⁷ Oxygen therapy is indicated for patients with an arterial oxygen tension (P_{aO_2}) of less than 55 mm Hg. The therapeutic goal is to maintain oxygen saturation greater than 90% during rest, sleep, and exertion, as it is now well established that such measures increase survival and that 24 hours is more effective than 12 hours. There is a clear rationale for the use of oxygen in severe COPD. Enhancing blood oxygenation by increasing the concentration of inspired oxygen compensates for a major physiologic consequence of COPD with hypoxemia. Oxygen remains the mainstay of initial therapy in most COPD exacerbations. Relief of hypoxemia, and

Box 39.2 General Management of Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Adjust O_2 to SpO_2 goal 88% to 92%
Initiate and maintain β -agonist and anticholinergic agents combined
Start prednisone 50 mg/day for 7 days
Start antibiotics if signs of infection

consequently of hypoxemic pulmonary vasoconstriction, decreases pulmonary vascular resistance, with variable effects on the ventilation/perfusion ratio.^{78,79} Oxygen delivery may increase as a result of increases in oxygen arterial content and anticipated improved right-sided heart function. However, one study demonstrated that relief of hypoxemia did not increase cardiac output.⁸⁰

Hypercapnia is well tolerated when it is chronic.⁸¹⁻⁸³ However, oxygen should be administered cautiously in patients who are chronically hypercapnic because it is known to lead to clinically significant rises in PaCO_2 in select COPD patients as a result of changes in the physiologic dead space and perhaps suppression of the respiratory drive.^{84,85} Acute increases in PaCO_2 are more likely to occur in patients with elevated baseline PaCO_2 . A randomized study has shown that, although oxygen administration worsened hypercapnia and respiratory acidosis, these changes were well tolerated in most patients.⁸⁶ Oxygen therapy should not be withheld in acutely ill hypoxemic patients because tissue hypoxia can lead to acute organ dysfunction. However, oxygen should be initiated at a low FIO_2 and slowly titrated up as necessary with vigilant monitoring to document improvement and stabilization in PaO_2 , with special attention paid to maintaining the oxyhemoglobin between 88% and 92% or greater without producing dangerous falls in pH as a result of rises in CO_2 . These dangerous rises in PaCO_2 are typically associated with worsening mental status. Nasal cannulas or Venturi masks can be used to initiate a low FIO_2 . Either nasal cannula at a flow rate of 1 L/minute or a Venturi mask initially at the lowest setting (25%) is appropriate for initiating oxygen in patients known or suspected to be chronic CO_2 retainers. However, in the presence of acute severe hypoxemia in patients with impending respiratory failure, high-flow oxygen therapy may be in the patient's best interest, regardless of the risk for CO_2 retention.⁸⁷

DRUG TREATMENT

BRONCHODILATORS

Bronchodilator therapy has important roles in both the prevention and treatment of AECOPD. Bronchodilators are the primary treatment to alleviate patient symptoms, improve physiologic state, and prevent or reverse respiratory failure; however, its use has not been shown to improve survival. Systematic reviews have demonstrated that inhaled delivery of short-acting β_2 -selective agonists and anticholinergic agents have greater effect on spirometry and is the therapy of choice for AECOPD over parenteral bronchodilators.⁸⁸ Bronchodilator treatment in acutely ill COPD patients has been shown to decrease inspiratory muscle loading, with an increase in FEV_1 and a decrease in functional residual capacity (FRC) and dynamic hyperinflation.⁸⁹ In mechanically ventilated patients, a reduction in expiratory resistance and dynamic hyperinflation (measured as a decrease in PEEPi) has been described.⁹⁰

There is no evidence supporting the use of one inhaled β_2 -selective agonist over another. There is no difference in outcome between β_2 -agonist compared with ipratropium bromide and no evidence that the combination of these two drugs is any more effective in AECOPD; these results are in contrast with the greater efficacy of these combinations in

stable COPD.⁸⁸ The widespread use of inhaled β -agonists has been accompanied by clinical concern of cardiac complications in elderly patients and those with coronary artery disease. However, in a study performed on clinically stable COPD or asthma patients with a history of myocardial ischemia, no ischemic events, or dysrhythmias, were observed when commonly used doses of salbutamol were administered.⁹¹ To date, no clinical studies have evaluated the use of inhaled long-acting bronchodilators (either β_2 -agonist or anticholinergic agents) with or without inhaled corticosteroids during AECOPD.

Several studies have suggested that the combination of β_2 -agonists and anticholinergic agents prevent exacerbations, particularly long-acting agents.⁹²⁻⁹⁶ It is possible that these agents reduce exacerbation frequency as a result of the effect on reduction of dynamic hyperinflation at rest and exercise,⁹⁷ as well as nonbronchodilator mechanisms, such as anti-inflammatory effect.⁹⁸

Intravenous methylxanthines (theophylline or aminophylline) are considered second-line therapy, only to be used in selected cases when there is insufficient response to short-acting bronchodilators. Side effects of methylxanthines are significant and the clinical response is inconsistent.

CORTICOSTEROIDS

COPD is recognized as an inflammatory disorder, and the severity of airway inflammation correlates with the severity of the underlying COPD.⁹⁹ During exacerbations, there is a large increase in concentration of proinflammatory cells, including neutrophils. Systemic corticosteroids improve lung function significantly, shorten hospital stay, and reduce the risk for relapses as compared with placebo in patients with AECOPD.¹⁰⁰ In the ISOLDE trial, the median exacerbation rate was reduced by 25%, and there was also a reduction in the health status deterioration.¹⁰¹ Systemic corticosteroids have been demonstrated to improve respiratory mechanics in mechanically ventilated patients, with a decrease in airway resistance and dynamic air-trapping.¹⁰² A meta-analysis demonstrated that the use of systemic corticosteroids was associated with significant reduction in treatment failure, defined as either clinical deterioration, withdrawal from the study due to unsatisfactory clinical improvement, or relapse of exacerbation symptoms during the follow-up period. It also showed beneficial effects in reducing the length of hospitalization by a weighted mean of 1.42 days.¹⁰³

Oral corticosteroids have beneficial effects in the management of AECOPD. Prednisolone, administered at 30 mg/day for 14 days, shortened the length of hospitalization by 2 days, improved FEV_1 by 60 mL/day, and accelerated recovery from symptoms.¹⁰⁴ The majority of patients with COPD probably requires only 2 weeks with oral corticosteroids and therapy for 8 weeks produced no incremental benefits above those achieved at 2 weeks.¹⁰⁵ One of the most important concerns regarding the use of corticosteroids in AECOPD is the possibility of confusing it with community-acquired pneumonia. Nevertheless, there is no evidence that corticosteroid use worsened the prognosis of community-acquired pneumonia if appropriate antibiotics are used; moreover, systemic corticosteroids may reduce morbidity and mortality rates in community-acquired pneumonia.¹⁰⁶

The use of inhaled corticosteroids is associated with decrease in exacerbation events by 12% to 25%.¹⁰⁷ Studies involving inhaled corticosteroids and long-acting β_2 -agonist showed reduction in exacerbation frequency to a greater extent than using either corticosteroid or long-acting β_2 -agonist alone.^{108,109} There is also a trend toward mortality rate reduction over 3 years of 17.5%, although without statistical significance.¹¹⁰ There is no evidence that the addition of inhaled corticosteroids to systemic corticosteroids in AECOPD has any impact either in recovery or in mortality rate.

ANTIBIOTICS

Use of antibiotics in AECOPD remains a controversial topic, with some authors recommending antibiotic therapy and others not, maybe in part because of the heterogeneity of the population studied.^{111,112} Compared with placebo, antibiotic use during AECOPD reduced treatment failures by 46%, defined as requiring additional antibiotics within the first 7 days or unchanged or deteriorated symptoms within 21 days. Antibiotics reduced treatment failures particularly in those patients who were hospitalized but not when they were used in ambulatory patients.¹¹³ Three clinical trials involving 181 patients demonstrated that in-hospital mortality rate can be reduced by 78% with the use of antibiotics during AECOPD.^{114,115} Patients who present with dyspnea and increased sputum volume or purulence or patients who require mechanical ventilation benefit from a 3- to 7-day course of oral or parenteral antibiotics.¹¹⁶

Although routine sputum cultures are recommended in all patients with AECOPD, invasive techniques (transtracheal aspirates,^{117,118} bronchoscopic aspirates, or protected specimen brushing^{5,119-123}) are not indicated. Exceptions include culture-negative community-acquired pneumonia not responding to therapy and ventilator-associated pneumonia (VAP).^{124,125} Because many COPD patients have airway colonization by bacteria, without clinical signs of infection and exacerbation, there is no clear significance of a positive culture in a COPD patient; however, in the presence of exacerbation associated with an alteration in sputum character or quantity, potentially pathogenic organisms grown from sputum should be covered with an appropriate antibiotic.¹²⁶ Thus, the selection of empiric antibiotics to treat AECOPD should depend on the severity of underlying disease and severity of COPD exacerbation. Therapy for more severe exacerbations should include coverage for antibiotic-resistant bacteria, such as *Pseudomonas* or methicillin-resistant *Staphylococcus aureus*.

HEMODYNAMIC SUPPORT

FLUID MANAGEMENT

COPD patients often have chronic pulmonary hypertension, which may worsen with COPD exacerbation because of hypoxic vasoconstriction, dynamic lung hyperinflation, and in mechanically ventilated patients, PEEP. This may lead to acute or worsening right ventricular failure. In one study, the prevalence of right ventricular failure in terminal COPD patients was 66% and the prevalence of left ventricular failure was only 6%.¹²⁷ As in other patients with right ventricular failure, hemodynamic stability is related to maintenance of mean arterial pressure. Mean systemic pressure

can potentially be increased in these patients by increasing intravascular volume or by selectively improving compliance of the pulmonary vascular bed.¹²⁸ Intravenous fluid challenge is the initial step in hemodynamic support in the presence of hemodynamic compromise. Despite the presence of peripheral edema, diuretics should be avoided, given the potential to induce loss of intravascular volume, decreased venous return, decreased cardiac output, and hypotension.

Likewise, because pulmonary hypertension produces chronically elevated right ventricular pressures, fluid challenge could potentially worsen the hemodynamic status of patients with cor pulmonale. Overzealous fluid administration may raise right ventricular pressure to the point that it produces a shift in the interventricular septum and a reduction in left ventricular compliance and filling. Currently, no consensus or guidelines exist concerning invasive pulmonary artery catheterization in this group of patients; however, in patients remaining hypotensive after initial volume challenge or in patients with organ perfusion abnormalities and biventricular failure, invasive monitoring may be clinically useful.

INOTROPES AND VASODILATORS

In patients who remain hemodynamically unstable despite fluid therapy, adrenergic therapy is advised. Although some literature recommends adrenergic therapy for right ventricular failure using norepinephrine^{129,130} or dobutamine,¹³¹ we could find no controlled trials of adrenergic drug therapy in hemodynamically unstable COPD patients. However, pulmonary embolism patients have a hemodynamic derangement similar to that of COPD patients with right ventricular failure, and as such, dobutamine seems a reasonable choice in attempts to increase right ventricular function and increase cardiac output in the normotensive patient with decreased tissue perfusion. In the presence of hypotension, dobutamine would be used in combination with a combined inotrope vasopressor such as norepinephrine or dopamine. Nitroglycerine has been shown in one study to enhance right ventricular performance when added to dobutamine.¹³² Nitroglycerine should be administered cautiously in patients who may have suboptimal right ventricle filling. Digoxin has no anticipated clinical utility in right ventricular failure, unless it is associated with left ventricular failure or arrhythmias that respond to digoxin.¹³³⁻¹³⁵

Although vasodilators have been used in clinical trials of COPD with right ventricular failure,¹³⁶⁻¹⁴³ there is no consistent evidence of clinical outcome benefit. Inhaled nitric oxide, a selective pulmonary vasodilator with a short half-life and no systemic vasodilator properties, has shown variable results in patients with AECOPD.¹⁴⁴⁻¹⁴⁸

NUTRITIONAL SUPPORT

Chapter 82 deals with overall nutritional support of the critically ill patient. Highlights of some issues directly related to the COPD patient follow.

Malnutrition has been recognized as a factor that increases mortality rate^{149,150} in COPD. Weight gain has been associated with decreased mortality rate.¹⁵¹ Nutritional status tends to decline markedly during acute illness in COPD patients,¹⁵²⁻¹⁵⁴ and patients may not recover to their previous

nutritional state during convalescence, with recurrent exacerbations leading to a stepwise decline in nutritional status over time.¹⁵⁵ Recent studies have shown that skeletal muscle mass is directly related to muscle dysfunction in COPD patients.¹⁵⁶ Nutritional status has been correlated with weaning outcome.¹⁵⁷ Short-term studies of oral supplemental feeding or enteral feeding have demonstrated increases in body weight and improvement in immunologic markers and respiratory muscle function.¹⁵⁸⁻¹⁶⁰ Nutritional support has been demonstrated to produce improvement in lung function in hospitalized patients with acute exacerbation of COPD.¹⁶¹

Special care must be taken to avoid overfeeding patients with COPD exacerbation because excess calories, particularly if carbohydrate rich, elevate total oxygen consumption and CO₂ production, which may complicate management in patients with hypercapnia.¹⁶² In one study of mechanically ventilated patients, enteral nutrition was administered with a fixed carbohydrate content and an association between total caloric intake and CO₂ production when providing nutritional support to the COPD patient with acute respiratory failure (ARF) was noted. It has been recommended that enteral alimentation provide total calories from 1.25 to 1.3 times the resting energy expenditure of the patient with a respiratory quotient target of 0.7 to 0.8 and that carbohydrate calories be limited to 40% of total calories.¹⁶³

NONINVASIVE MECHANICAL VENTILATION

ARF in the setting of AECOPD is characterized by the worsening of hypoxemia and a variable degree of carbon dioxide retention and acidemia. Worsening in ventilation/perfusion ratio (\dot{V}/\dot{Q}) mismatching is probably the leading mechanism in the occurrence of the hypoxemia by the enlargement of physiologic dead space and the rise of wasted ventilation.¹⁶⁴ The increase in airway resistance and the need of a higher minute ventilation may result in expiratory flow limitation, dynamic hyperinflation, and related PEEP_i with subsequent increased inspiratory threshold load and dysfunction of the respiratory muscles, which may lead to their fatigue.¹⁶⁵ Dyspnea, right ventricular failure, and encephalopathy characterize severe AECOPD complicated by ARF. Arterial pH reflects the acute worsening of the alveolar ventilation, and, regardless of the chronic level of PaCO₂, it represents the best marker of the ARF severity.¹⁶⁶

Those patients with severe AECOPD develop ARF requiring ventilatory support. The frequency of this support varies among series, being as high as 74%.¹⁶⁷ Ventilatory support may be of two types: invasive and noninvasive. Noninvasive ventilation (NIV) using nasal masks or facemasks has proved efficacious in ARF caused by COPD in several clinical studies, with success rates as high as 65% in some series.¹⁶⁸⁻¹⁷⁰ As with invasive mechanical ventilation, the goals of NIV include respiratory muscle rest, ventilatory support during treatment of reversible conditions, and the correction of severe hypoxemia and hypercarbia.

Several prospective, randomized, controlled studies confirmed the clinical efficacy of NIV in the treatment of the ARF during AECOPD. Compared to standard medical therapy alone the application of NIV improves survival,

reduces the need for endotracheal intubation and the rate of complications, and shortens length of stay in hospital and intensive care unit (ICU).^{167,170,171}

INDICATIONS

Patients with mild exacerbation, with normal or mildly reduced pH (pH > 7.35) and without clinical signs of respiratory failure, do not appear to benefit from a trial of NIV.¹⁷²

In patients with moderate ARF, characterized by pH levels between 7.25 and 7.30, NIV is indicated for a few hours per day (<12 hours/day) in order to prevent endotracheal intubation, with low failure rates (15% to 20%), and appear to have the greater benefit.¹⁷³

In more severely ill patients (pH < 7.25), the rate of NIV failures is inversely related to respiratory acidosis. In this population, the use of NIV as an alternative to invasive ventilation does not affect the mortality rate or the duration of ventilatory support, but it is associated with a lower rate of complications (VAP, difficult weaning). Despite the elevated rate of failure, it is worth a short trial of NIV if no contraindication is present (decreased level of consciousness, cardiac or respiratory arrest, severe gastrointestinal bleeding, severe hemodynamic instability, facial surgery or trauma, upper airway obstruction, inability to clear secretions).¹⁷⁴

IMPLEMENTATION OF NONINVASIVE POSITIVE-PRESSURE VENTILATION

NIV is usually delivered in assisted ventilation modality but no differences in success rate were found when applied in controlled ventilatory modality.¹⁷⁵ Leak is a constant feature of NIV and may affect triggering of the ventilator, delivered FIO₂, and air humidification. As such, the choice of the interface is one of the crucial issues affecting NIV outcome; although facemask is the standard interface to deliver NIV in patients with ARF, poor mask tolerance, skin lesions, and leaks are reported among factors causing NIV failure and intubation requirement.¹⁷⁶

The nasal mask has less dead space, causes less claustrophobia, minimizes potential complications in case of vomiting, and allows both expectoration and oral intake of fluids without the need to remove the mask. However, facemasks are preferable in severely dyspneic patients because the nasal resistance to breathing is decreased with combined nose and mouth air entry. Also, opening of the mouth during nasal noninvasive positive-pressure ventilation produces loss of tidal volume, which decreases effectiveness. In our opinion, the facemask is optimal for initial use in most patients with severe respiratory distress.

The use of pressure support ventilation (PSV) is the most common mode of ventilation for application of NIV. Nonetheless, bilevel positive airway pressure has become the preferred mode of NIV administration in COPD patients because it is generally as comfortable as PSV but produces greater improvement in gas exchange and reduces the work of breathing more effectively than PSV alone.¹⁷⁷⁻¹⁷⁹ Specifically designed noninvasive bilevel ventilators will have a better leak tolerance and adjust trigger and cycle sensitivity to improve patient-ventilator synchrony.¹⁸⁰

The goal of NIV is to provide ventilatory support to rest fatigued respiratory muscles while the underlying illness is

treated. The use of adequate ventilatory support is important regardless of the ventilator and modality chosen to deliver NIV. When using pressure-cycled modes, the recommended approach is to start at low pressures for patient comfort and titrate the pressure support or inspiratory positive airway pressure (IPAP) to achieve a tidal volume of at least 6 mL/kg, improvement in clinical signs (RR < 25 beats per minute, reduced accessory muscle use), and patient comfort.¹⁸¹ External PEEP, referred to as expiratory positive airway pressure (EPAP) in bilevel ventilators, may counteract PEEPi, and thus aid triggering, reduce oxygen consumption, and improve comfort. Although PEEPi can be as high as 15 cm H₂O in patients with severe AECOPD, EPAP levels higher than 5 cm H₂O are rarely tolerated or necessary. Therefore, slow titration to patient comfort is important to maximize the likelihood of NIV success. Improvements in pH, PaCO₂, and level of consciousness at 60 minutes are predictors of success in patients on AECOPD who respond to NIV.¹⁷⁸

The British Thoracic Society recommended that patients with ARF who respond to NIV be maintained as continuously as possible during the first 24 hours. If the respiratory status has stabilized, then the duration of ventilatory support can be reduced on subsequent days. Masks are removed for meals, conversation, comfort, and respiratory treatment as necessary.¹⁸²

WEANING

Weaning from NIV may be accomplished either by progressively decreasing the levels of inspiratory positive-pressure support or by permitting the patient to be intermittently off NIV for increasing lengths of time. A combination of both strategies can also be used. In general, it is useful to wean patients by progressively increasing the period of spontaneous breathing without NIV. Once the acute process improves, many patients can be weaned relatively quickly. Unlike invasive ventilation, NIV can be reinstituted easily and quickly if the patient shows signs of fatigue or intolerance to spontaneous breathing. The use of nocturnal NIV may be needed during the early weaning period and may be continued at home in some patients.¹⁸³

Some studies have analyzed weaning outcome in intubated patients with AECOPD, comparing NIV with conventional weaning methods. Results showed that NIV reduced weaning time, shortened intensive care days, decreased the incidence of nosocomial pneumonia, and improved 60-day survival rates.^{184,185} NIV has also been used successfully in another study on patients with hypercarbia after extubation.¹⁸⁶ A meta-analysis concluded that, notwithstanding, the use of NIV to facilitate weaning, in mechanically ventilated patients, with predominantly COPD, is associated with promising but insufficient evidence of clinical benefit at present.¹⁸⁷

INVASIVE MECHANICAL VENTILATION

Patients requiring immediate admission to the ICU are those who presented with severe dyspnea that responds inadequately to initial emergency therapy, with changes in mental status (confusion, lethargy, coma), persistent or

worsening hypoxemia (PaO₂ < 40 mm Hg), and/or severe or worsening respiratory acidosis (pH < 7.25) despite supplemental oxygen and NIV, hemodynamic instability with the need of vasopressors, and the need for invasive mechanical ventilation.

Invasive ventilation is indicated for patients who are not suited for NIV or who failed NIV, respiratory or cardiac arrest, respiratory pauses with loss of consciousness or gasping for air, altered level of consciousness (from psychomotor agitation to coma), massive aspiration, persistent inability to remove respiratory secretions, severe hemodynamic instability without response to fluids and vasopressors, severe ventricular arrhythmias, and life-threatening hypoxemia in patients unable to tolerate NIV. Patients with AECOPD requiring invasive mechanical ventilation have a higher ICU mortality rate and in-hospital mortality rate when compared with nonventilated patients.¹⁸⁸

INITIAL APPROACH AND MAINTENANCE

VENTILATION MODES

Mechanical ventilation of patients with AECOPD should be targeted to decrease excessive respiratory work. Patient-triggered ventilation modes, either assist-control or synchronized intermittent mandatory ventilation (SIMV), typically accomplish this goal. Special care must be taken; however, if these modes are not adequately adjusted to fit the characteristics of the patient, an increase in respiratory work will result.¹⁸⁹

PSV has been extensively used and reviewed in the literature.^{190,191} In AECOPD patients, PSV has been shown to decrease inspiratory effort as the applied pressure is increased; however, the response among patients varied significantly.¹⁸⁰ At higher levels of support pressure, many patients show an activation of the respiratory muscles during the late phase of inflation, with the potential to produce ventilation dyssynchrony. This may be more common in patients with longer time constants and those who require higher inspiratory flows delivered for longer periods.¹⁹²

We recommend that ventilation be provided as total support during the initial phase of respiratory management (assist-control volume ventilation or high-level PSV).

INSPIRED OXYGEN

The goal of oxygenation should be to maintain an oxyhemoglobin saturation of at least 90% to 92%. In dark-skinned patients, pulse oximetry may overestimate oxyhemoglobin saturation, and in these patients, we recommend targeting pulse oximetry values of 95% to ensure adequate oxygenation. Although there is no clear-cut clinical evidence that allows determination of the FIO₂ threshold of concern for oxygen toxicity, based on animal studies of oxygen toxicity in normal lungs, attempts to lower FIO₂ to 0.6 or less by the end of the first 24 hours of mechanical ventilation is a reasonable goal.¹⁹³

INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

Before discussing ventilation settings in AECOPD complicated with ARF, a review of intrinsic PEEP (PEEPi, auto-PEEP, dynamic hyperinflation) is in order. The two primary pathophysiologic changes that contribute to the

development of respiratory distress and ARF in patients with obstructive lung disease are increased expiratory airflow resistance and dynamic hyperinflation. In COPD, the alveolar attachments that normally keep the smaller airway open via radial traction are lost. This leads to airway narrowing and collapse especially during expiration. In AECOPD the already narrowed airways may be further compromised by increased secretions, mucosal swelling, and peribronchial inflammation. The time constant for lung emptying is prolonged and end-expiratory lung volume is dynamically increased. Therefore, the next inspiratory effort occurs before the expiratory phase is completed, leading to air-trapping, and the respiratory system is prevented from returning to its resting state at the end of the expiration and thus dynamic hyperinflation develops. Dynamic hyperinflation results in PEEPi.¹⁹⁴ Initially, PEEP is beneficial because it maintains the airways open, thereby reducing the airway resistance.

PEEPi is typically not detected on the pressure gauge of the ventilator because it is open to the atmosphere except for a very brief moment at the end of expiration. If the expiration port of the circuit is occluded at end expiration in a relaxed patient with a delay of next inspiration, the pressure inside the lungs and in the circuit will begin to equilibrate; if occlusion is sufficiently prolonged, PEEPi may be recorded.¹⁹⁵

PEEPi has numerous hemodynamic and mechanical consequences. When PEEPi is excessive, barotrauma may occur. Hemodynamic consequences of PEEPi effect are more common with decreased venous return, decreased stroke volume, and hypotension. PEEPi also increases the work of breathing, which is represented by an increase of workload during spontaneous inspiration and by an increase in the threshold of ventilator triggering. PEEPi is treated by increasing expiratory time and decreasing the minute ventilation, as well as reducing the airflow resistance by bronchodilators and corticosteroids. This effect is achieved by decreasing the respiratory rate and tidal volume.

INSPIRATORY TRIGGERING SENSITIVITY SETTINGS

The setting of the optimal triggering threshold is more difficult in COPD patients, especially if dynamic lung hyperinflation exists. This is because the patient needs to generate a negative pressure equal to PEEPi before interfacing with the preset sensitivity on the ventilator. When PEEPi is high, the patient may exert significant inspiratory effort before the triggering threshold is reached, another cause of dyssynchrony. On the other hand, if the sensitivity of the ventilator has been placed at a very sensitive level, the ventilator may cycle inappropriately and can cause serious respiratory alkalosis, especially in the absence of significant PEEPi. Many ventilators have flow-triggered options, and although theoretically flow triggering may reduce patient effort, some reports failed to show differences when flow triggering is compared with newer pressure-triggering devices, even in COPD patients, although it is known that flow-triggered ventilators work better when the patient has elevated requirements of inspiratory flow.^{196,197}

INSPIRATORY FLOW RATE

High inspiratory flow rate helps satisfy the demands of most dyspneic or tachypneic COPD patients; moreover, it

decreases the likelihood of dynamic hyperinflation and PEEPi. This decreases inspiratory time and increases expiratory time, minimizing PEEPi. An improvement in gas exchange has been found when inspiratory flows were increased from 40 to 60 L/minute in COPD patients.¹⁹⁸

TIDAL VOLUME

In patients with known or suspected PEEPi, smaller tidal volumes (6 to 8 mL/kg) may be necessary to prevent alveolar overdistention, dynamic hyperinflation, and barotrauma.

RESPIRATORY RATE

In the presence of PEEPi or in patients with high risk of developing PEEPi, elevations in respiratory rate must be avoided because expiratory time will be significantly decreased. Although SIMV with low spontaneous tidal volume may control minute ventilation, it has variable effects on PEEPi and may significantly increase respiratory workload. For these reasons, controlled mechanical ventilation with optimal sedation and even muscular paralysis may be the optimal approach.

POSITIVE END-EXPIRATORY PRESSURE

In the past, PEEP was avoided in patients with AECOPD because of the concern of worsening dynamic hyperinflation. It is now recognized that the application of extrinsic PEEP below 75% to 85% of PEEPi may facilitate ventilator triggering, because alveolar pressure now needs to be decreased to only below the level of the external PEEP, instead of below the level of atmospheric pressure, decreasing the work required to trigger the inspiration.^{199,200}

The key points to optimize mechanical ventilation in AECOPD include recognition of the presence of worsening of expiratory airflow limitation and consequent dynamic hyperinflation, reducing the dynamic hyperinflation and PEEPi by providing the longest expiratory time possible, reducing patient ventilatory demands and minute ventilation and reducing the airway flow limitation with bronchodilators and corticosteroids, adjusting the minute ventilation to correct the pH but not the CO₂ to minimize hyperventilation, and keeping the plateau pressure below 30 cm H₂O to minimize barotrauma.

WEANING

In general, restoration of respiratory muscle function requires approximately 24 to 48 hours of mechanical ventilation.²⁰¹⁻²⁰³ Before weaning patients with AECOPD from mechanical ventilation, the premonitory condition that triggered ARF should be corrected and an adequate neuromuscular competency/workload ratio achieved. Therefore, the strategy for facilitating weaning from the ventilator should include an increase in inspiratory force and a decrease in the load on the respiratory system. See Chapter 43 for a comparison of various weaning techniques.

EXTUBATION TO NONINVASIVE VENTILATION

Earlier studies have supported the idea that NIV can facilitate weaning and improve outcomes in difficult-to-wean patients by avoiding the complications of prolonged intubation. There is evidence that the use of NIV as a method of

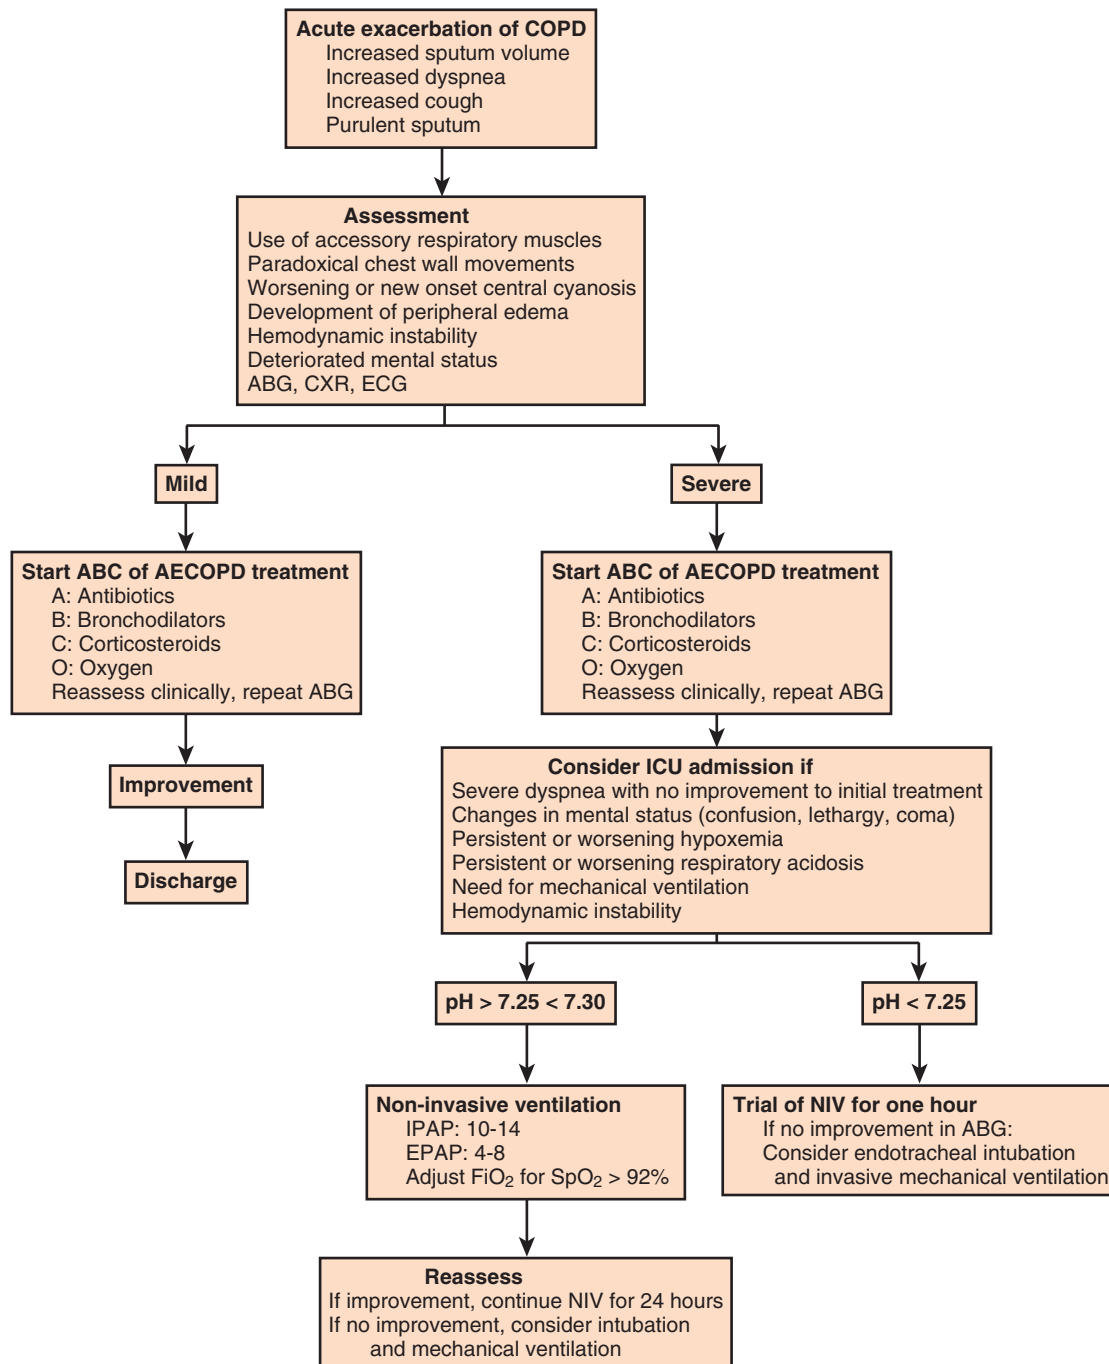

Figure 39.1 Management of acute exacerbations of chronic obstructive pulmonary disease.

weaning in patients with AECOPD and CHF resulted in shorter periods of intubation, decreased length of hospital and ICU stay, lower rate of nosocomial pneumonia, and improved ICU and 90-day survival.

Figure 39.1 is a suggested algorithm for the management of the AECOPD.

PROGNOSIS

The outcome for the patients with AECOPD with ARF depends on the severity of the COPD, the trigger for ARF,

and avoidance of ICU complications. In patients who require mechanical ventilation for acute exacerbation, the overall in-hospital mortality rate is greater than 20%.²⁰⁴ For elderly patients, the mortality rate is greater than 50%.²⁰⁵ In a multicenter study of patients aged 65 or older, the mortality rate was 30% at hospital discharge, 41% at 90 days, 47% at 180 days, and 59% at 1 year. The time course and recovery following COPD exacerbation in a cohort of 101 patients with a mean FEV₁ of 41.9% has been reported.²⁰⁶ Patients recorded daily morning peak expiratory flow rate (PEFR) following the onset of the exacerbation. Median recovery time for PEFR was 6 days. Recovery of PEFR to baseline

values was complete in only 75.2% of exacerbations at 35 days, and 7.1% of exacerbations had still not returned to baseline at 91 days.²⁰⁶

TERMINAL CARE FOR THE END-STAGE PATIENT

All patients with severe end-stage COPD should be well educated about their prognosis and limitations of therapy. Some patients may elect not to be mechanically ventilated when the COPD is in the late stage and the likelihood of extubation is extremely low. Others may choose short-term ventilation only in the hope of a reversible cause. Others may choose long-term ventilation with tracheostomy and home or special facility mechanical ventilation. It is important that emotional and psychological support be given for the end-stage patient and his or her family.

KEY POINTS

- Worldwide, COPD is the only leading cause of death that still has a rising mortality rate, and it has been estimated that by the year 2020, COPD will be fifth among the most burdensome conditions to society.
- The fundamental physiologic abnormality in AECOPD is worsening of expiratory airflow limitation and consequent dynamic hyperinflation.
- Abdominal muscles are recruited during expiration in severe COPD patients. Dynamic hyperinflation can be overestimated during chronic and acute airway obstruction if abdominal muscle function is not evaluated.
- Although the precise cause of acute exacerbation is poorly understood, it has been associated with a number of precipitating factors, including infection, either bacterial or viral; environmental factors; pulmonary embolism; medication failure; and patient noncompliance.
- Acute increases in PaCO₂ with administration of supplemental oxygen are more likely to occur in patients with elevated baseline PaCO₂.
- The cornerstone of treatment of airway flow limitation in AECOPD is based on the ABCs: antibiotics, bronchodilators, and corticosteroids.
- A combination of inhaled short-acting β_2 -agonists and inhaled anticholinergics is indicated during exacerbations to alleviate patient symptoms.
- When a metered-dose inhaler (MDI) is used for acute exacerbations, the addition of a spacing device, which enhances lower airway drug deposition, is indicated to ensure adequate drug delivery.
- In patients with severe respiratory distress, nebulizers are still the best option to ensure optimal drug delivery.
- Systemic corticosteroids shorten recovery time; improve lung function (FEV₁) and arterial hypoxemia; and

KEY POINTS (Continued)

- reduce the risk of relapse, treatment failure, and length of hospital stay. Treatment with corticosteroids should be maintained for 10 to 14 days.
- Antibiotics should be given to patients with AECOPD who have an increase in dyspnea, sputum volume, and sputum purulence or who require mechanical ventilation.
- The choice of antibiotics should be based on the local bacterial pattern, and the recommended length of antibiotic therapy is usually 5 to 10 days.
- Nutritional support has been demonstrated to produce improvements in lung function in hospitalized patients with AECOPD.
- NIV reduces the rate of intubation and mortality rate in selected patients with ARF secondary to AECOPD. The highest benefit occurs in patients with moderate ARF with pH between 7.25 and 7.3.
- Potential physiologic benefits of NIV in AECOPD include improvement in tidal volume, gas exchange, respiratory rate, heart rate, oxygenation, and diaphragm activity, as well as a reduction in arterial CO₂ with a concomitant improvement in pH. When these beneficial responses occur, they are typically seen in the first several hours after beginning NIV.
- ICU admission for patients with AECOPD is recommended in patients with severe dyspnea that responds inadequately to initial emergency therapy, changes in mental status, persistent or worsening hypoxemia or persistent or worsening respiratory acidosis despite NIV, the need for mechanical ventilation, and hemodynamic instability.
- If the expiration port of the circuit is occluded at end expiration in a relaxed patient with a delay of next inspiration, the pressure inside the lungs and in the circuit will begin to equilibrate; if occlusion is sufficiently prolonged, PEEPi may be recorded.
- PEEPi has numerous hemodynamic and mechanical consequences.
- To reduce dynamic hyperinflation and PEEPi, provide the longest expiratory time possible, reduce patient ventilatory demand and minute ventilation, and reduce airflow resistance by using bronchodilators and corticosteroids.

Hypoventilation and Respiratory Muscle Dysfunction

Franco Laghi

CHAPTER OUTLINE

DECREASED NEUROMUSCULAR CAPACITY

Decreased Respiratory Center Output
Respiratory Muscle Weakness
Respiratory Muscle Fatigue

INCREASED LOAD

Increased Mechanical Load
Increased Ventilatory Requirements

HYPERCAPNIA-INDUCED HYPOVENTILATION
SUMMARY

Hypercapnic respiratory failure is conventionally defined as a state in which ventilation is insufficient to maintain an arterial tension of carbon dioxide (P_{aCO_2}) of less than 45 mm Hg for the level of metabolic activity (measured by CO_2 production, $\dot{V}CO_2$).¹ Under steady-state conditions, the relationship among P_{aCO_2} , alveolar ventilation (\dot{V}_A), and $\dot{V}CO_2$ is given by the equation:

$$P_{aCO_2} = (\dot{V}CO_2 / \dot{V}_A) \times K$$

in which K (usually stated as 0.863) is a constant that converts measurement of $\dot{V}CO_2$ from standard conditions to body temperature conditions. The term \dot{V}_A represents the portion of minute ventilation (\dot{V}_E) that reaches the terminal gas exchange units and is calculated as

$$\dot{V}_A = \dot{V}_E - \dot{V}_D$$

where \dot{V}_D equals dead space ventilation. A reduction in \dot{V}_A may result from an inadequate \dot{V}_E or an increase in \dot{V}_D (resulting from an increase in true \dot{V}_D or a functional increase in \dot{V}_D secondary to lung regions with high ventilation-perfusion [\dot{V}_A/\dot{Q}] relationships).*

Hypercapnia is synonymous with alveolar hypoventilation for the patient's level of carbon dioxide production. Alveolar hypoventilation can result from decreased neuromuscular capacity and increased respiratory load (Fig. 40.1).² Isolated impairments in gas exchange—i.e., conditions in

which the alveolar-arterial O_2 gradient* is increased—usually do not cause hypercapnia.³ When gas exchange is impaired, however, the magnitude of neuromuscular derangements causing hypercapnia or the magnitude of increased respiratory loads causing hypercapnia is less than the corresponding derangements when gas exchange is normal. Conditions in which gas exchange contributes to hypercapnia are usually characterized by ventilation-perfusion inequality. When gas exchange is impaired total minute ventilation may actually be increased despite a concurrent decrease in alveolar ventilation.

DECREASED NEUROMUSCULAR CAPACITY

Disease states that may result in decreased neuromuscular capacity and thus in alveolar hypoventilation include

*The alveolar-arterial O_2 gradient ($A-aDO_2$) is calculated as $PAO_2 - PaO_2$, in which PAO_2 (alveolar O_2 tension) can be estimated according to the simplified alveolar gas equation:

$$PAO_2 = FIO_2 \times (P_B - P_{H_2O}) - PaCO_2 / R$$

where FIO_2 = fractional concentration of inspired O_2 (about 0.21 when breathing room air), P_B = barometric pressure (about 760 mm Hg at sea level), P_{H_2O} = water vapor pressure (usually taken as 47 mm Hg at 37°C), and R = respiratory exchange ratio of the whole lung. The respiratory exchange ratio (R) = CO_2 production/ O_2 consumption ($\dot{V}CO_2/\dot{V}O_2$). R is normally about 0.8. In steady state, R is determined by the relative proportions of free fatty acids, protein, and carbohydrate consumed by the tissues. In this equation, it is assumed that alveolar PCO_2 and P_{aCO_2} are the same (usually they nearly are). In healthy young subjects (≤ 30 years old) breathing air at sea level, $A-aDO_2$ is usually less than 10 mm Hg, but it increases to as much as 28 mm Hg in healthy 60-year-old subjects.¹

*Terminology of dead space is confusing. *Anatomic dead space* is made up of the conducting airways (nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles). *Alveolar dead space* is made up of alveoli that receive some or no blood flow, which does not match ventilation (units with very high \dot{V}_A/\dot{Q} ratio). *Physiologic dead space* is the sum of anatomic dead space and alveolar dead space.¹

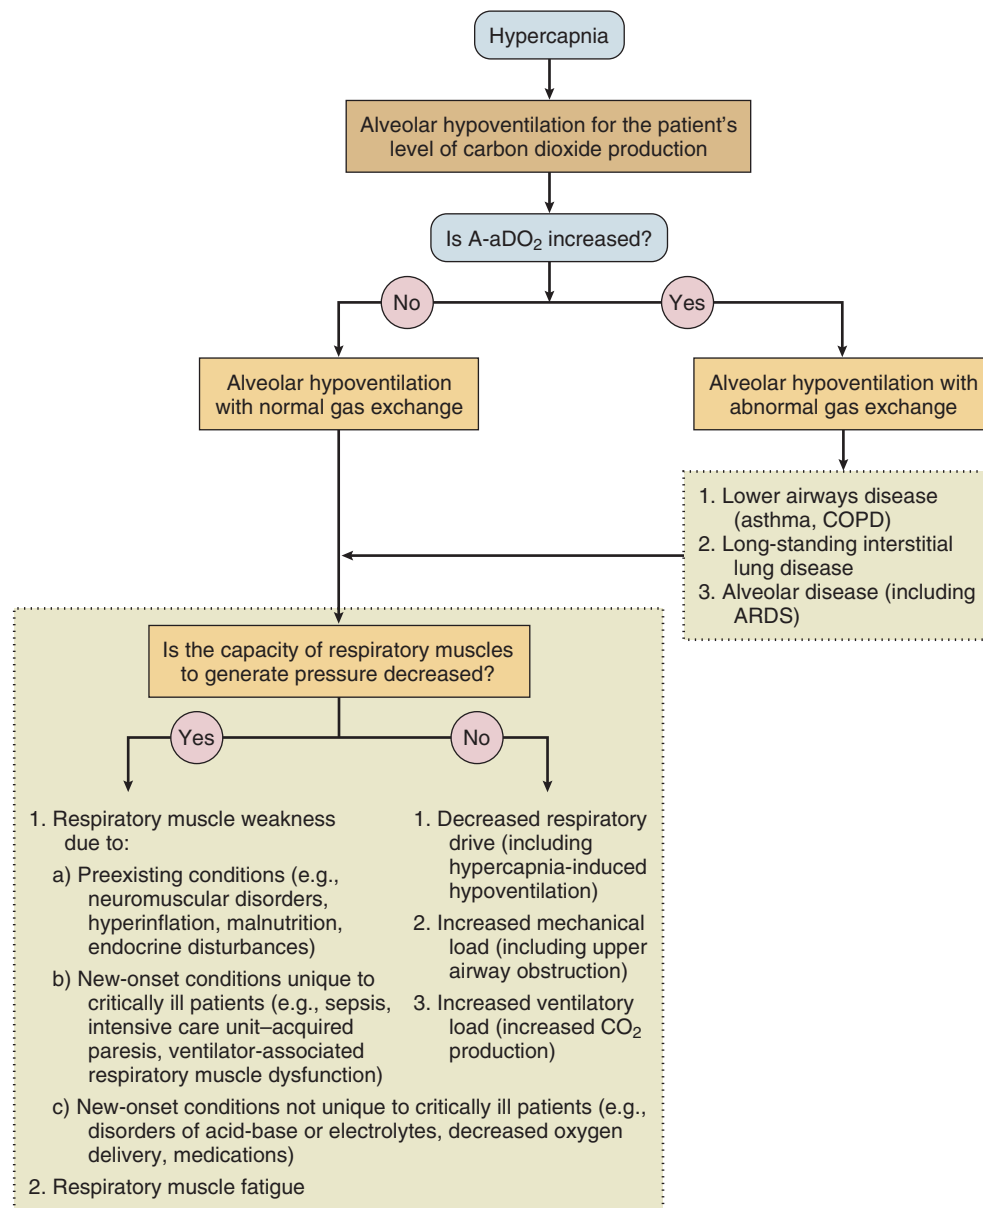

Figure 40.1 Diagnostic approach to critically ill patient with hypercapnia. A-aDO₂, alveolar-arterial difference in partial pressure of oxygen; ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.

conditions characterized by decreased respiratory center output and by respiratory muscle weakness and respiratory muscle fatigue.

DECREASED RESPIRATORY CENTER OUTPUT

Isolated decreases in respiratory drive can produce ventilatory failure without distress. Potential causes include sedative overdose,¹ hypothyroidism,⁴ metabolic alkalosis,⁵ semistarvation,⁶ and central alveolar hypoventilation syndrome. The latter can be either idiopathic (i.e., primary alveolar hypoventilation, or Ondine's curse) or secondary to neurologic lesions, such as trauma, infection (poliomyelitis), infarction, and obesity hypoventilation syndrome.⁴ In mechanically ventilated patients, decreases in respiratory drive are suspected when patients develop marked increases in PCO₂ despite relatively normal measurements of

resistance and elastance and no apparent evidence of lower motor neuron disease.⁷ Whether sleep deprivation decreases respiratory drive remains controversial.^{8,9}

RESPIRATORY MUSCLE WEAKNESS

DETECTION OF RESPIRATORY MUSCLE WEAKNESS IN CRITICALLY ILL PATIENTS

Measurements of airway pressure during maximal voluntary inspiratory efforts are used to evaluate global inspiratory muscle strength.¹⁰ In healthy subjects, maximum inspiratory airway pressure is usually more negative than −80 cm H₂O.¹⁰ In mechanically ventilated patients recovering from an episode or acute respiratory failure, maximum inspiratory airway pressure can range from less negative than −20 cm H₂O to about −100 cm H₂O.^{7,11,12} Values of maximal airway pressure during voluntary maneuvers depend greatly on a

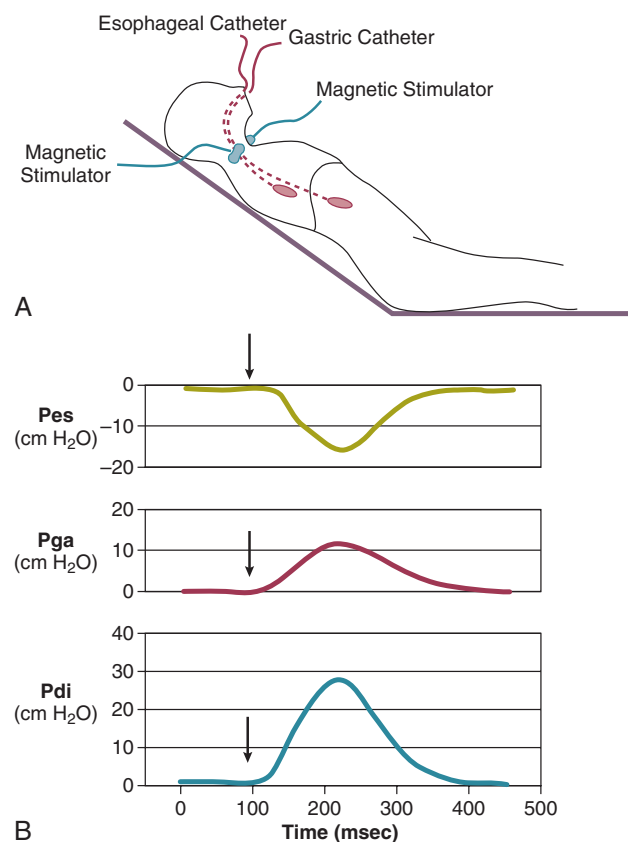

Figure 40.2 Recording of transdiaphragmatic twitch pressure. **A**, An esophageal balloon and a gastric balloon are passed through the nares. Magnetic stimulation of the phrenic nerves elicits diaphragmatic contraction. **B**, Continuous recordings of esophageal (Pes) and gastric pressures (Pga) and transdiaphragmatic pressure (Pdi)—calculated by subtracting Pes from Pga. Phrenic nerve stimulation (arrows) results in contraction of the diaphragm with consequent fall in intrathoracic pressure (negative deflection of Pes) and rise in intra-abdominal pressure (positive deflection of Pga). These swings in pressure are responsible for the transdiaphragmatic twitch pressure. The smaller the transdiaphragmatic twitch pressure, the smaller the force generation capacity of the diaphragm.

level of motivation and comprehension of the maneuver (often not obtainable in critically ill patients).¹³ Not surprisingly, in patients requiring short-term mechanical ventilation, measurements of maximum inspiratory airway pressure commonly do not differentiate between weaning success and weaning failure patients.¹²⁻¹⁴

In contrast to the voluntary nature of maximal voluntary inspiratory efforts, transdiaphragmatic pressures elicited by single stimulations of the phrenic nerves—or twitch pressure—are independent of patients' motivation and eliminate the influence of the central nervous system.¹⁰ Activation can be achieved with either an electrical stimulator¹⁵ or a magnetic stimulator,¹⁵ though the latter is easier to use in mechanically ventilated patients (Fig. 40.2).^{13,16,17}

In healthy volunteers, magnetic stimulation elicits twitch pressures that average 31 to 39 cm H₂O.¹⁰ In patients with severe chronic obstructive pulmonary disease (COPD), twitch pressures average 19 to 20 cm H₂O.^{18,19} The value of transdiaphragmatic twitch pressure in patients recovering from an episode of acute respiratory failure is about one

Figure 40.3 Transdiaphragmatic pressure in response to single stimulations (twitch stimulation) of the phrenic nerves recorded in ventilated patients recovering from acute respiratory failure. The boxed area represents the 95% confidence interval of values obtained in healthy subjects. The decreased transdiaphragmatic twitch pressure in patients indicates presence of diaphragmatic weakness. (From Laghi F: Ventilator-induced diaphragmatic dysfunction: Is there a dim light at the end of the tunnel? Crit Care Med 2011;39:903.)

third of that recorded in healthy subjects (Fig. 40.3).²⁰ This marked reduction in twitch pressure^{16,17} indicates the presence of respiratory muscle weakness in most of these patients. Respiratory muscle weakness in critically ill patients can result from preexisting conditions or from new-onset conditions.

WEAKNESS DUE TO PREEXISTING CONDITIONS

Neuromuscular diseases, malnutrition, endocrine disorders, and hyperinflation are some of the preexisting conditions that can cause respiratory muscle weakness. The existence of preexisting conditions can be recognized before the patient develops acute ventilatory failure, at the time the patient develops acute ventilatory failure, or when acute ventilatory failure is already established.^{4,21-24}

Neuromuscular Disorders

The capacity of the respiratory muscles to generate tension can be decreased in certain disorders, such as stroke, amyotrophic lateral sclerosis, spinal cord injuries, poliomyelitis, Guillain-Barré syndrome, neuropathies due to massive intoxications of arsenic²⁵ or thallium,²⁶ chronic inflammatory demyelinating polyneuropathy, axonopathy of acute intermittent porphyria, myasthenia gravis, acid maltase deficiency, and muscular dystrophies such as myotonic dystrophy (i.e., the most frequent adult form of muscular dystrophy).^{4,27,28}

Hypercapnic respiratory failure usually occurs when respiratory muscle strength falls to 39% of the predicted normal value.²⁹ However, Gibson and associates³⁰ described several patients with neuromuscular disease who had a normal partial pressure of CO₂ despite decreases in respiratory muscle strength to less than 20% of predicted. Conversely, some patients with only moderate respiratory muscle weakness displayed hypercapnia (Fig. 40.4).³⁰ In other

Figure 40.4 Relationship between muscle strength and mixed venous partial pressure of CO₂ (P_{vcO₂}) in patients with respiratory muscle weakness. Respiratory muscle strength is the arithmetic sum of maximum static inspiratory and expiratory mouth pressures (P_{max} = P_{imax} + P_{emax}). The open circles are patients with myotonic dystrophy, and the closed circles are patients with a variety of nonmyotonic muscle diseases. As respiratory muscle weakness became more severe P_{vcO₂} rose, although considerable variability was observed among patients. The regression lines were similar in the myotonic and nonmyotonic patients. (From Gibson GJ, Gilmartin JJ, Veale D, et al: Respiratory muscle function in neuromuscular disease. In Jones NL, Killian KJ [eds]: *Breathlessness. The Campbell Symposium*. Hamilton, Ontario, Boehringer-Ingelheim, 1992.)

words, reductions in muscle strength do not consistently predict alveolar hypoventilation in this setting.

Hyperinflation

Hyperinflation is a common preexisting problem in patients with obstructive lung diseases such as COPD,⁴ cystic fibrosis,³¹ bronchiolitis,³² and lymphangioliomyomatosis.⁴ The severity of preexisting hyperinflation commonly worsens in patients experiencing an exacerbation of COPD.³³ Hyperinflation has a number of adverse effects on inspiratory muscle function: the inspiratory muscles operate at an unfavorable position of the length-tension relationship (Fig. 40.5);³⁴ flattening of the diaphragm decreases the size of the zone of apposition with the result that diaphragmatic contraction causes less effective rib cage expansion.⁴ Hyperinflation also has an adverse effect on the elastic recoil of the thoracic cage.⁴ This means that the inspiratory muscles must work not only against the elastic recoil of the lungs but also against that of the thoracic cage. The functional consequences of dynamic hyperinflation are probably the main mechanisms of ventilatory failure in patients with COPD.³⁵ Hyperinflation can also occur de novo in patients with pneumonia, chest trauma, and acute respiratory distress syndrome (ARDS).^{33,36} Impairment of inspiratory muscle function is less likely in patients with ARDS than in patients with obstructive lung disease because patients with ARDS breathe at a low lung volume despite dynamic hyperinflation.^{36,37}

Malnutrition

Malnutrition is highly prevalent among critically ill patients requiring mechanical ventilation,^{38,39} and it is associated with poor prognosis.³⁹ Malnutrition decreases muscle mass

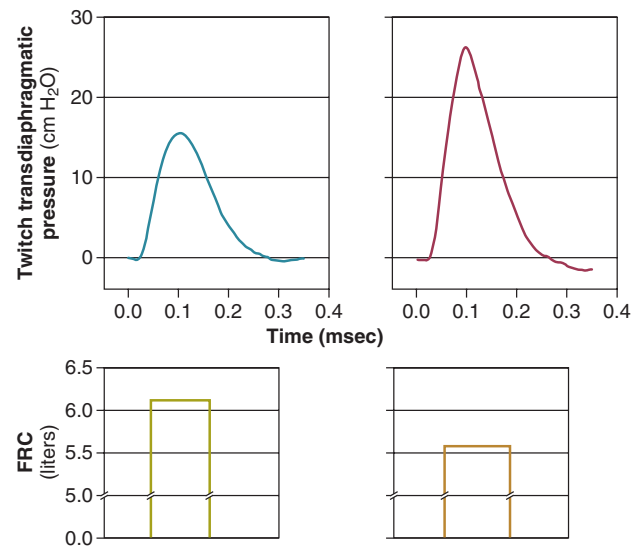

Figure 40.5 Twitch transdiaphragmatic pressure elicited by phrenic nerve stimulation (*upper panels*) and functional residual capacity (FRC) (*lower panels*) in a patient with severe emphysema before (*left*) and after (*right*) lung volume reduction surgery. The increase in transdiaphragmatic pressure after surgery was in part due to a decrease in the operating lung volume as demonstrated by the decrease in functional residual capacity. (Data from Laghi F, Jubran A, Topeli A, et al: Effect of lung volume reduction surgery on neuromechanical coupling of the diaphragm. *Am J Respir Crit Care Med* 1998;157:475.)

and respiratory muscle strength both in humans^{40,41} and in laboratory animals.⁴²⁻⁴⁴ Likely mechanisms contributing to decrease in respiratory muscle mass include proteolysis of myofibrillar proteins by the ubiquitin-proteasome proteolytic system (Fig. 40.6) and apoptosis.^{4,45} Apoptosis can be triggered by local and circulating tumor necrosis factor- α and by release of cytochrome *c* from the mitochondria.^{46,47}

In patients with COPD, inspiratory muscle strength is about 30% less in poorly nourished patients than in well-nourished patients with equivalent airway obstruction.⁴⁸ Similarly, malnourished patients with anorexia nervosa can present with reduced inspiratory muscle strength to 35% to 50% predicted,⁴¹ impaired respiratory muscle endurance,⁴⁹ impaired hypercapnic ventilatory response,⁴⁹ and occasionally, with hypercapnia at rest.⁴¹ In malnourished patients, inspiratory weakness,^{41,48,49} fatigability,⁴⁸ and dyspnea⁴⁸ are partially reversible with nutritional support. The process is slow and, in laboratory animals, can take months of refeeding for muscle mass to return to normal values.⁵⁰ To date, it remains unclear whether malnutrition by itself can cause sufficient respiratory muscle weakness to produce hypoventilation. It is more likely for malnutrition to be a contributory factor and not a sole cause of hypercapnic respiratory failure.

Endocrine Disturbances

Endocrine disturbances such as hypothyroidism,⁵¹ hyperthyroidism,^{47,52-54} and acromegaly⁵⁵ can adversely affect respiratory muscle function. Proteolysis of myofibrillar proteins by the ubiquitin-proteasome proteolytic system⁴⁵ (see Fig. 40.6) is probably responsible for respiratory muscle catabolism and weakness of hyperthyroidism.⁴⁷ This mechanism is implicated in muscle wasting associated with acidosis, renal

Figure 40.6 Ubiquitin-proteasome degradation of contractile proteins. The first step in degradation of actin and myosin is activation of ubiquitin (Ub) by a first enzyme, E₁—a process requiring adenosine triphosphate (ATP). Activated ubiquitin interacts with a second enzyme, E₂, a carrier protein. Ub and E₂ join a third enzyme, E₃. E₃ transfers activated Ub to actin and myosin. The cycle is repeated until a chain of Ub is bound to the contractile proteins. The chain of Ub binds to one end of a proteasome complex in a process requiring ATP. The Ub chain is subsequently removed (allowing reuse of Ub), and actin and myosin are unfolded and pushed into the core of the proteasome. Multiple enzymes within the core degrade actin and myosin into small peptides. The peptides are extruded from the proteasome and degraded to amino acids by peptidases in the cytoplasm. The ubiquitin-proteasome system degrades myofibrillar proteins only after they have been cleaved and released by other proteolytic pathways—i.e., the ubiquitin-proteasome pathway cannot degrade intact myofibrillar proteins. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48.)

failure, denervation, cancer, diabetes, acquired immunodeficiency syndrome (AIDS), trauma, and burns.⁴⁵ In contrast to other endocrine disturbances, respiratory muscle weakness is unusual in patients with Cushing syndrome.⁵⁶

WEAKNESS DUE TO NEW-ONSET CONDITIONS

New-onset respiratory muscle weakness in critically ill patients may result from conditions that are unique to these patients. These conditions include ventilator-associated respiratory muscle dysfunction, sepsis-associated myopathy, and intensive care unit (ICU)-acquired paresis. New-onset respiratory muscle weakness can also result from conditions that are not unique to critically ill patients, including acid-base disorders, electrolyte disturbances, decreased oxygen delivery, and certain medications. Respiratory muscle weakness due to conditions that are unique to critically ill patients are often associated with alterations in respiratory muscle structure, although the others are not necessarily associated with alterations in muscle structure. Recovery from respiratory muscle weakness (if it occurs at all) is slow when the weakness is caused by alterations in muscle structure. In contrast, recovery of respiratory muscle weakness in conditions that are not necessarily associated with alterations in muscle structure is usually quick once the underlying triggering factor has been corrected.

Ventilator-Associated Respiratory Muscle Dysfunction

Since the late 1980s, several groups have studied the effect of mechanical ventilation on the muscles of laboratory animals.⁵⁷ A seminal study by Anzueto and colleagues⁵⁸ showed that 11 days of controlled mechanical ventilation (CMV) together with neuromuscular blocking agents produced a 46% decrease in respiratory muscle strength (Fig. 40.7). Subsequent studies have revealed that complete cessation of diaphragmatic activity with CMV—alone⁵⁹ or in combination with neuromuscular blocking agents⁶⁰—results in atrophy and injury of diaphragmatic fibers (Fig. 40.8). Muscle fibers generate less force in response to stimulation, not simply because of their decreased bulk but even when normalized for cross-sectional area.⁵⁷ The decrease in diaphragmatic force ranges from 20% to more than 50%. The alterations in muscle function occur rapidly, within 12 hours of instituting mechanical ventilation,⁶¹ and they appear to increase as ventilator duration is prolonged.^{62,63}

Mechanical ventilation may also harm the respiratory muscles of patients. In 1988, Knisely and coworkers⁶⁴ reported that the cross-sectional area of diaphragmatic fibers in infants who had died after receiving mechanical ventilation for 12 or more days was much smaller than that in infants who had received mechanical ventilation for 7 days or less (Fig. 40.9). Fibers taken from extradiaphragmatic muscles were similar in the two groups. Twenty years later, Levine and associates⁶⁵ obtained biopsies of the diaphragm from 14 brain-dead organ donors who were maintained on CMV for 18 to 69 hours. They also obtained intraoperative biopsies of the diaphragms of eight control patients who had received CMV for 2 to 3 hours. Histologic measurements revealed marked diaphragmatic atrophy in the brain-dead patients. Compared with the control group, the mean cross-sectional areas of muscle fibers were decreased by more than 50%. A number of these results

Figure 40.7 Transdiaphragmatic pressure (Pdi) response to phrenic nerve stimulation before (solid line) and after 11 days (dashed line) of mechanical ventilation. That the Pdi recorded after 11 days of mechanical ventilation shows a decreased response to all stimulation frequencies is suggestive of ventilator-associated diaphragmatic dysfunction (Modified from Anzueto A, Peters JL, Tobin MJ, et al: Effects of prolonged controlled mechanical ventilation on diaphragmatic function in healthy adult baboons. *Crit Care Med* 1997;25:1187.)

have been corroborated by Jaber and colleagues⁶³ and Hermans and coworkers,⁶⁶ who also reported a progressive decrease in diaphragmatic contractility of mechanically ventilated patients. The decrease in contractility correlated with the duration of ventilator support (Fig. 40.10).^{63,66}

Biochemical and gene-expression studies in animals and humans^{65,67} suggest that oxidative stress is probably one of the most proximal mechanisms in the biochemical cascade that leads to ventilator-induced muscle injury.⁶⁸ Oxidative stress decreases contractility by causing protein oxidation and by promoting protein catabolism⁶⁸—including up-regulation of the autophagy-lysosome pathway.⁶⁹ The synergism between ventilator-induced muscle injury and oxidative stress has caused investigators to explore whether early administration of antioxidants might minimize muscle injury.⁷⁰⁻⁷² In a study of more than 200 critically ill patients—80% of whom required acute ventilator support—duration of mechanical ventilation was nearly 3 days shorter in those who completed a 10-day antioxidant supplementation protocol (vitamin E and vitamin C) than in those who completed a 10-day course of placebo.⁷³ Similar results have

Figure 40.8 Electron microscopy of the diaphragm (longitudinal section) of a rabbit under control conditions (A, specimen processed with 1100-mOsm fixative) and after 3 days of controlled mechanical ventilation (B, specimen processed with 500-mOsm fixative). The control rabbit has an intact ultrastructure. The mechanically ventilated rabbit shows several areas of disrupted myofibrils (short thick arrows), the mitochondria are swollen (long thick arrow) and have abnormal cristae, and the intermyofibril space contains lipid droplets (long thin arrow), indicating decreased lipid uptake by the mitochondria. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48. Electron micrographs provided by Dr. Catherine S. H. Sassoon, Long Beach VA Hospital and University of California, Irvine, CA.)

Figure 40.9 Photomicrographs of transverse sections of diaphragm from an infant ventilated from birth until death at day 47 (A) and from an infant ventilated from birth until accidental death at day 3 (B). Prolonged mechanical ventilation was associated with reduction in myofiber cross-sectional area. (The yellow arrow indicates a developing myofiber also known as Wohlfart myofiber.) (Modified from Knisely AS, Leal SM, Singer DB: Abnormalities of diaphragmatic muscle in neonates with ventilated lungs. *J Pediatr* 1988;113:1074.)

Figure 40.10 Twitch airway pressure elicited by magnetic stimulation of the phrenic nerves in six patients who received mechanical ventilation (MV) for 30 minutes (short-term MV; open bar) and in six patients who received MV for about 6 days (long-term MV; solid bars). On day 1 twitch airway pressure was already less in the long-term than in the short-term MV group. In addition, long-term MV was associated with a progressive decrease in twitch pressure over time—mean reduction of $32 \pm 6\%$ after 6 days of MV. H, number of hours of mechanical ventilation; D, number of days of mechanical ventilation. (From Jaber, Petrof BJ, Jung B, et al: Rapidly progressive diaphragmatic weakness and injury during mechanical ventilation in humans. *Am J Respir Crit Care Med* 2011;183:364-371.)

been reported in critically ill surgical patients requiring mechanical ventilation.⁷⁴ Whether the decrease in duration of mechanical ventilation was, at least in part, due to the potential positive effects of antioxidants on the respiratory muscles remains to be demonstrated. Of concern, however, was the report that administration of the antioxidant *N*-acetylcysteine (NAC) to critically ill patients with severe sepsis worsened sepsis-induced organ failure.⁷⁵

In animal models, ventilator settings can affect the extent of ventilator-associated respiratory muscle dysfunction.⁷⁶⁻⁷⁹ In rabbits, assist-control mechanical ventilation causes a nonsignificant decrease in diaphragm muscle contractility, which contrasts with the 48% decrease recorded with CMV.⁷⁶ Similar results have been obtained when comparing CMV to adaptive support ventilation in piglets⁷⁸ or when comparing CMV to pressure support in rats⁷⁹ or CMV to intermittent spontaneous breathing again in rats.⁷⁷ These observations raise the important question of whether maintenance of partial diaphragmatic activity or intermittent loading of the diaphragm could prevent the harm done to diaphragmatic function by mechanical ventilation.⁸⁰

Considering that decrease in protein synthesis probably contributes to ventilator-associated respiratory muscle dysfunction,^{81,82} it would seem biologically plausible that administration of anabolic factors—such as growth hormone—might be of benefit in ventilated patients. Unfortunately, when growth hormone has been administered to patients requiring prolonged mechanical ventilation, duration of mechanical ventilation was not decreased, nor was muscle strength increased.⁸³ Of concern was the report that recombinant growth hormone can increase the mortality rate of critically ill patients.⁸⁴ An even more fundamental point in regard to ventilator-associated respiratory muscle dysfunction has been raised recently by the preliminary data of Hooijman and associates.⁸⁵ These investigators measured the contractile properties of single diaphragmatic fibers

obtained from nine brain-dead organ donors who had received CMV for 30 to 84 hours (case subjects) and from nine patients undergoing surgery for localized lung cancer (control subjects). In this preliminary study no difference was noted between the muscle fibers of the two groups of patients with respect to maximum force per unit area, calcium sensitivity of contractile force, and rate constant of redevelopment of force (*K*_{tr}). How to reconcile the preliminary results of Hooijman and associates⁸⁵ with previous data obtained on muscle strips from animal models and by phrenic nerve stimulation in patients remains to be determined.

Sepsis-Associated Myopathy

Sepsis, a common occurrence in critically ill patients, can produce ventilatory failure by causing respiratory muscle dysfunction and increased metabolic demands.⁸⁶ Septic animals develop failure of neuromuscular transmission (due to increased sarcolemmal electric potential)⁸⁷⁻⁸⁹ and failure of excitation-contraction coupling.^{86,90} Mechanisms responsible for failure of excitation-contraction coupling include the cytotoxic effect of nitric oxide and its metabolites, free radicals, ubiquitin-proteasome proteolysis, and possibly, decrease in nicotinic acetylcholine receptors.^{91,92} Local dysregulation of the circulation and Krebs cycle may also contribute.⁸⁶

Nitric oxide, a free radical that has a negative inotropic effect in the heart and skeletal muscle, is produced in large amounts during sepsis by a nitric oxide synthase inducible by lipopolysaccharide and several cytokines (Fig. 40.11).⁹³ Increased expression of inducible nitric oxide synthase in the diaphragm during sepsis is associated with morphologic evidence of widespread damage to the myofiber membrane, or sarcolemma (Fig. 40.12).⁸⁸ Diaphragmatic contractions enhance this sepsis-induced sarcolemmal injury,⁹⁴ while early mechanical ventilation decreases sarcolemmal injury and the associated diaphragmatic dysfunction.⁹⁵ The beneficial effects of resting the diaphragm with the use of mechanical ventilation are not coupled with a decrease in oxidative stress or with a decrease in the expression of inducible nitric oxide synthase in the muscle.⁹⁵ These observations suggest the existence of a detrimental interaction of two independent stressors (oxidative and biomechanical stresses) on the sarcolemma during sepsis.⁹⁵

To determine whether the inducible nitric oxide synthase pathway contributes to impaired skeletal muscle contractility in humans, Lanone and coworkers⁹⁶ obtained samples of the rectus abdominis in 16 septic patients and 21 control subjects. The muscles of the patients had lower contractile force, and increases in inducible nitric oxide synthase expression (mRNA and protein) and activity. Immunohistochemical studies revealed the generation of peroxynitrite (a highly reactive oxidant formed by the reaction of nitric oxide with superoxide anion). Exposure of control muscles to the amount of peroxynitrite found in patients caused an irreversible decrease in force generation. These data suggest that sepsis decreases muscle force through the production of nitric oxide and its toxic byproducts.

Production of nitric oxide in sepsis may be protective and not solely deleterious.^{94,97-99} In mice deficient in inducible⁹⁷ or constitutive (neuronal) nitric oxide synthase,⁹⁴ endotoxin caused a greater decline in diaphragmatic contractility

Figure 40.11 **A**, A sample of gastrocnemius muscle obtained from an adult Sprague-Dawley rat injected 12 hours earlier with *Escherichia coli* endotoxin (20 mg/kg). The section was stained with an antibody to inducible nitric oxide synthase. Positive staining (brown coloration, arrows) is evident inside the fibers. **B**, A sample of gastrocnemius muscle obtained from a rat injected 12 hours earlier with normal saline. No positive staining is evident. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48. Photomicrographs provided by Dr. Sabah N. Hussain, Royal Victoria Hospital, Montreal, Canada.)

Figure 40.12 **A**, A strip of diaphragm obtained from a C57BL/6 mouse injected 12 hours earlier with normal saline. The strip was stimulated for 3 minutes (50 Hz, 300-ms duration) and then immersed for 90 minutes in Krebs solution containing a fluorescent probe, Procion orange 14 (0.15, wt/vol). **B**, A strip of diaphragm obtained from a C57BL/6 mouse injected 12 hours earlier with *Escherichia coli* endotoxin (20 mg/kg). Stimulation and staining were conducted as described in A. Sarcolemmal damage, indicated by yellow staining, was increased by endotoxin. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48. Photomicrographs provided by Dr. Sabah N. Hussain, Royal Victoria Hospital, Montreal, Canada.)

than in nondeficient mice. This finding contrasts with the observation that nitric oxide synthase inhibitors prevent muscle dysfunction in septic rats.^{88,93,100} Although the results may be species-dependent,⁹⁴ the data underscore that nitric oxide has both antioxidant and pro-oxidant actions.¹⁰¹

In addition to nitric oxide and its derivatives, several other oxygen-derived free radicals (superoxide anion, hydroxyl radicals, hydrogen peroxide) contribute to the decreased contractility of the diaphragm in sepsis.^{99,102-104} This increased expression of oxygen-derived free radicals in sepsis is accompanied with enhanced activity of the antioxidant enzyme superoxide dismutase¹⁰² and with increased expression of the heme oxygenase-1 pathway.¹⁰⁴ The heme oxygenase-1 pathway is a powerful cellular system that protects against oxidative stress and contractile fatigue during sepsis.¹⁰⁴ Administration of an inhibitor (zinc protoporphyrin IX) or an inducer (hemin) of heme oxygenase activity respectively enhances or reduces the oxidative stress and

contractile failure of the diaphragm in a rat model of sepsis.¹⁰⁴ In septic rats, decreased diaphragmatic contractility can also be improved by the administration of specific scavengers of superoxide ions, hydrogen peroxide, and hydroxyl radicals.¹⁰²

Intensive Care Unit-Acquired Paresis

While cared for in the ICU, critically ill patients can develop muscle weakness and, occasionally, paralysis. Some of these patients have evidence for axonal degeneration and denervation atrophy (Fig. 40.13).⁴ This constellation of findings is known as critical illness polyneuropathy (Table 40.1).¹⁰⁵ Cytokines¹⁰⁶ and low-molecular-weight neurotoxins¹⁰⁷ released during episodes of sepsis or when patients develop multiple organ failure are thought to be responsible for this axonal degeneration. Critical illness polyneuropathy has been considered one of the manifestations of multiple organ failure syndrome. Sepsis and multiple organ

Figure 40.13 Transverse section of a peripheral motor nerve (deep peroneal nerve, **A**) and of a skeletal muscle (intercostal, **B**) in patients who developed profound weakness following a prolonged hospital course characterized by sepsis, multiple organ failure syndrome, and inability to wean from mechanical ventilation. **A**, The long thin dark structures seen in the left panel are myelin sheaths that contain axons. The axons are degenerating and dying. Following death, they disintegrate. The myelin surrounding the disintegrating axons collapses around the axonal debris to form ovoids of myelin—seen better on the lateral portions of the left micrograph. **B**, Amid muscle fibers that are normal in size and shape there are atrophic ones that appear small and that have developed contours with acute angles. These findings are consistent with denervation atrophy secondary to axonal degeneration, so-called critical illness polyneuropathy. (From Zochodne DW, Bolton CF, Wells GA, et al: Critical illness polyneuropathy. A complication of sepsis and multiple organ failure. *Brain* 1987;110:819.)

failure, though, are not essential prerequisites for the development of critical illness polyneuropathy.^{108,109} Tight control of hyperglycemia may reduce the risk of polyneuropathy and the duration of mechanical ventilation.¹¹⁰

In other patients, rather than axonopathy, there is evidence of isolated myopathy (i.e., critical illness myopathy).⁴ Patients developing isolated myopathy often have been treated with steroids and neuromuscular blocking agents (e.g., patients with status asthmaticus).⁴ Muscle biopsies demonstrate a general decrease in myofibrillar protein content and a selective loss of thick filaments (myosin) within type I and type II fibers (Table 40.2 and Fig. 40.14). Animal models of critical illness myopathy suggest that medical denervation with paralytic agents cause an up-regulation of glucocorticoid receptors in the muscle.¹¹¹ If the animal subsequently receives high-dose corticosteroids, it will develop depletion of thick myosin filaments.¹¹¹ Although a decrease in thick-filament proteins may be important for prolonged weakness,¹¹² this decrease is probably not the cause of the acute paralysis,¹¹³ particularly in patients with compound motor action potentials of

low amplitude.¹¹⁴ Impaired muscle membrane excitability is probably more important during the acute stage.^{113,115}

In the last few years it has become increasingly apparent that critical illness neuropathy and myopathy often coexist.^{106,109,115-118} It has become common to refer to patients who become weak while in the ICU as a result of acquired neuropathy or myopathy (not associated with a known disorder) as simply having ICU-acquired paresis.^{115,116,118} In patients with ICU-acquired paresis duration of weaning from mechanical ventilation can be two to seven times longer than in patients without ICU-acquired paresis.¹¹⁹

The functional outcome of ICU-acquired paresis is not uniform. Approximately 50% to 60% of patients experience complete recovery (ability to breathe spontaneously and to walk independently) over a period of 2 weeks to 6 months or longer.^{112,119,120} About 30% experience severe persistent disability with tetraparesis, tetraplegia, or paraplegia.¹¹⁹ Other investigators report even worse outcome: only 2 of 10 patients left the hospital in one study.¹¹⁷ Whether it is possible to prevent ICU-acquired paresis in patients recovering from severe acute illness, and whether that would result

Table 40.1 Examples of Electromyography (EMG) Findings in Respiratory Muscle Weakness

EMG Feature	Axonal Injury	Myelin Injury	Neuromuscular Conduction Defect	Myopathy
Compound muscle action potential (amplitude)*	Reduced	Normal to slightly reduced	Normal†	Normal
Sensory nerve action potential (amplitude)‡	Reduced	Normal to reduced	Normal	Normal
Conduction velocity	Normal to slightly reduced	Reduced	Normal	Normal
Spontaneous muscle depolarization§	Present	Absent	Absent	None to present
Amplitude of compound muscle action potential with stimulation at 3 Hz*	Unchanged	Unchanged	Decreased	Unchanged
Motor unit activation	Decreased	Decreased	Normal	Increased

Examples of injuries and deficits: *axonal injury*, critical illness polyneuropathy; *myelin injury*, Guillain-Barré syndrome; *neuromuscular conduction defect*, myasthenia, prolonged neuromuscular blockade; *myopathy*, critical illness myopathy.

*Elicited by motor nerve stimulation.

†Decreased in Lambert-Eaton syndrome.

‡Elicited by sensory nerve stimulation.

§Spontaneous muscle depolarization (caused by denervation) is detected by presence of fibrillation potentials and positive sharp waves.

*Repetitive nerve stimulation is performed to exclude neuromuscular transmission defects such as prolonged neuromuscular paralysis.

Although features of myopathy can be recorded by electromyographic studies, electromyography cannot always distinguish critical illness myopathy from critical illness polyneuropathy, and muscle biopsy may be needed.

From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10.

Table 40.2 Characteristics of Types of Muscle Fibers

Characteristic	Type I	Type IIa	Type IIx	Type IIb
Contractile Properties				
Velocity of shortening	+	++	+++	++++
Tetanic force	+	+	++	++
Endurance	++++	+++	++	+
Work efficiency*	+++	++	++	+
Histochemistry				
Mitochondrial volume density	+++	+++	++	+
ATP consumption rate	+	++	+++	++++
Oxidative enzymes	+++	+++	++	+
Glycolytic enzymes	+	++	+++	++++
Glycogen	+	++	++	+++
Capillary supply	+++	+++	++	+
Diameter	+	++	++	+++

*Amount of work performed per unit of adenosine triphosphate (ATP) consumed.

A single myosin heavy chain isoform typically is expressed within an adult skeletal muscle fiber. Fibers classified as type I, IIa, IIx, or IIb express myosin heavy chain isoform I (or slow), IIa, IIx, or IIb, respectively. Type IIx fibers have been reported in peripheral muscles of humans and animals and in the diaphragm of animals. Type IIx fibers have not been reported in the human diaphragm. More than one myosin heavy chain isoform is expressed in a few fibers (about 14% of adult rat diaphragm coexpresses myosin heavy chain isoforms IIb and IIx, and less than 1% coexpresses myosin heavy chain isoforms I and IIa).²²⁶ Whereas the velocity of muscle contraction depends primarily on the myosin heavy chain isoform, the velocity of muscle relaxation is mainly determined by troponin C calcium binding and release and by calcium reuptake by the sarcoendoplasmic reticulum calcium-adenosine triphosphatase (SERCA). Several SERCA isoenzymes have been identified: SERCA 1 is expressed in type II fibers (fast calcium reuptake), and SERCA 2a is expressed in type I fibers (slow calcium reuptake).²²⁷ The density of pumping sites largely accounts for different rates of calcium uptake in fast- and slow-twitch muscle fibers.²²⁷ Despite this separation of tasks, velocity of contraction and velocity of relaxation tend to parallel each other: type II fibers contract and relax with a greater velocity than type I fibers. Slower velocity of relaxation allows fusion of repetitive twitches at lower frequencies of stimulation than with fast relaxations. Impairment of SERCA activity has been implicated in the development of fatigue and in disease states including heart failure and corticosteroid myopathy.

From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10.

Figure 40.14 Electron micrographs of normal skeletal muscle (*right panel*) and skeletal muscle from a patient who received steroids and the neuromuscular blocking agent vecuronium during a hospitalization with status asthmaticus followed by flaccid quadriplegia. Compared with the normal structure, the patient developed extensive loss of thick (myosin) myofilaments and relative preservation of thin (actin) filaments. Muscle strength returned to normal 2 months after discontinuation of vecuronium. M, M-line formed by myosin filaments and M-line proteins; Z, Z-disk formed by a lattice of filaments that join the actin filaments of one sarcomere with the actin filaments of the adjacent sarcomere. (From Eisenberg BR: Can electron microscopy distinguish fiber types? In Bradley WG, Gardner-Medwin D, Walton JN [eds]: *Recent Advances in Myology*. Amsterdam, Excerpta Medica, 1975; and from Danon MJ, Carpenter S: Myopathy with thick filament (myosin) loss following prolonged paralysis with vecuronium during steroid treatment. *Muscle Nerve* 1991;14:1131.)

in shorter duration of mechanical ventilation remains unknown.

Acid-Base Disorders

Alkalosis, either metabolic or respiratory, does not affect skeletal muscle strength¹²¹⁻¹²³ and might improve endurance.¹²¹ Whether acidosis, either metabolic or respiratory, impairs respiratory muscle function remains controversial. Because the contractile response to metabolic and respiratory acidosis is not necessarily the same,^{124,125} metabolic acidosis and respiratory acidosis will be discussed separately.

Metabolic Acidosis. Until recently, there was little doubt that metabolic acidosis could decrease muscle contractility.^{126,127} Purported mechanisms included reduction of actin-myosin cross-bridge activation by H^+ competitive inhibition of Ca^{2+} binding to troponin-C, reduced transition of actin-myosin cross-bridges from low- to high-force state, inhibition of myofibrillar adenosine triphosphatase (ATPase), inhibition of glycolytic rate, inhibition of maximal shortening velocity, and inhibition of sarcoplasmic ATPase with reduction of sarcoplasmic Ca^{2+} reuptake leading to reduced Ca^{2+} release from the sarcoplasmic reticulum.¹²⁸ Despite the biologic plausibility, investigators have reported no effect^{125,129} or marginal effect¹³⁰ of metabolic acidosis on respiratory muscle function. Yanos and colleagues¹²⁵ assessed maximal transdiaphragmatic pressure elicited by tetanic stimulation of the phrenic nerves in seven anesthetized dogs during respiratory acidosis (pH 7.1) and during lactic acidosis (pH 7.1). They observed a fall in maximal diaphragm strength with respiratory acidosis (−18%, $p < 0.05$), but not with lactic acidosis (+3%). Similarly, when Coast and associates¹³⁰ exposed isolated diaphragm strips of rats to different concentrations of lactic acid they recorded decreases in force when the pH was lowered to 6.8—but only after the muscle strips were stressed with 75 contractions (25 Hz, 250-ms train duration, one train per second). Contractility

was not affected when the pH was decreased to ~7.0 at rest, and following the set of 75 contractions when delivered at a pH of 7.1 and 7.2.¹³⁰ These negative results are in line with some—but not all^{131,132}—recent investigations questioning the inhibitory role of metabolic acidosis on limb muscle contractility at physiologic temperatures.¹³³⁻¹³⁶ For instance, Nielsen and colleagues¹³⁶ reported that metabolic acidosis (pH 6.80) counteracts the detrimental effects of increased extracellular K^+ concentrations (which occur with forceful contractions) on the excitability and force generation of the rat soleus muscle. In humans, Degroot and coworkers¹³⁴ measured intracellular H^+ concentration during sustained isometric foot plantar flexion. In contrast to what would be expected if acidosis caused decrease in contractility, Degroot and coworkers¹³⁴ reported a decrease in intracellular H^+ concentration during the first 10 seconds of exercise when force was declining and a rise in intracellular H^+ concentration immediately after exercise, when force partially recovered.¹³⁴ Whether severe metabolic acidosis in humans might impair skeletal function by causing a reduced central nervous system drive remains to be demonstrated.¹²⁶

Acute Respiratory Acidosis. There are contrasting reports on the effect of acute respiratory acidosis on respiratory muscle contractility.^{122,123,125,137} In anesthetized dogs, diaphragmatic contractility decreases *pari passu* with the severity of acute respiratory acidosis¹²² (but has no effect on gastrocnemius muscle contractility).¹²⁵ Similarly, in healthy volunteers, acute increases of arterial carbon dioxide to 54 mm Hg (corresponding to a pH of about 7.29) reduces the capacity of the unfatigued diaphragm to generate pressure by 10% to 30% (Fig. 40.15).¹²³ Such reduction in pressure generation is even greater when arterial carbon dioxide is increased to 63 mm Hg (corresponding to a pH of about 7.22).¹²³ Acute respiratory acidosis can decrease respiratory muscle endurance,^{123,138} and it can increase the extent of

Figure 40.15 Transdiaphragmatic pressure (Pdi) and electrical activity of the diaphragm (Edi) during a voluntary isometric contraction in a healthy subject during normocapnia (*left panel*) and during acute hypercapnia (end-tidal CO_2 , 7.5%, *right panel*). For a given Edi during hypercapnia the pressure output of the diaphragm was decreased. (From, Juan G, Calverley P, Talamo C, et al: Effect of carbon dioxide on diaphragmatic function in human beings. *N Engl J Med* 1984;310:874.)

diaphragmatic fatigue at the conclusion of 2 minutes of maximal voluntary ventilation.¹³⁹ Despite greater voluntary activation of the diaphragm,¹⁴⁰ hypercapnic patients with COPD generate lower maximal static inspiratory pressures than patients with normocapnia.^{141,142}

A direct inhibitory effect of acute respiratory acidosis^{122,123,125,138,139} on respiratory muscle contractility and respiratory muscle endurance could provide a potential mechanism for the rapid clinical deterioration that can occur with severe asthma and during COPD exacerbations.¹²³ Yet, the human data suggesting a direct deleterious effect of acute respiratory acidosis on respiratory muscle function^{123,138,139,141} is not uniform. Some investigators report no change in diaphragmatic contractility^{137,139} (but decrease in force of the adductor pollicis)¹³⁷ when acute respiratory acidosis causes a decrease in pH to about 7.16 to 7.27,^{137,143} no change in the maximum relaxation rate of the diaphragm,¹⁴³ and no effect in the extent of diaphragmatic fatigue 20 to 90 minutes after loading.¹³⁹

For several reasons it is difficult to reconcile the conflicting data on the effects of acute respiratory acidosis on respiratory muscle contractility reported in the literature. First, the nonsignificant decrease in diaphragmatic contractility of 12% (twitch pressure) recorded during acute hypercapnia in 12 healthy subjects in one study¹³⁷ raises the possibility of type II error. Second, it is impossible to state that more severe acidosis was responsible for the different results in human investigations considering the comparable pH values of the negative¹³⁷ and positive¹²³ studies. Third, it is unlikely that different frequencies of stimulation used to assess the respiratory muscles^{123,137,139} are responsible for the contrasting results because, when present, acidosis-associated decrease in contractility is frequency independent.¹²² Moreover, three additional considerations further cloud our understanding of any interaction (if present) between acute respiratory acidosis and respiratory muscle contractility. First, respiratory acidosis (pH 6.50–6.88) may actually enhance and not depress skeletal muscle contractility.^{136,144} Second, it is unknown whether comorbid conditions, which often affect hypercapnic patients, such as sepsis, decreased cardiac function, and impaired respiratory mechanics could act synergistically with acute hypercapnia in worsening respiratory muscle function. Third, it is unknown whether equivalent levels of pH occurring as a result of acute- or acute-on-chronic respiratory acidosis may—or may not—have the same effect on respiratory muscle function.

Electrolyte Disturbances

Respiratory muscle function may be impaired by decreased levels of phosphate,¹⁴⁵ calcium,¹⁴⁶ magnesium,¹⁴⁷ and potassium.¹⁴⁸ Aubier and associates¹⁴⁵ studied the effects of severe hypophosphatemia (0.55 ± 0.18 mmol/L) on diaphragmatic function in eight patients with acute respiratory failure who were mechanically ventilated. Diaphragmatic function was quantified before and after phosphorus replacement therapy by recording transdiaphragmatic twitch pressure elicited by phrenic nerve stimulation. Correction of hypophosphatemia was accompanied by a significant increase in transdiaphragmatic twitch pressure—i.e., from 9.8 ± 3.8 cm H_2O before phosphate infusion to 17.3 ± 6.5 cm H_2O after phosphate infusion ($p < 0.001$). Changes in the serum phosphorus level and transdiaphragmatic pressure were well correlated ($r = 0.73$). These results strongly suggest that hypophosphatemia can impair the contractile properties of the diaphragm during acute respiratory failure.

The same investigators assessed the effects of hypocalcemia on diaphragmatic function in 12 anesthetized dogs.¹⁴⁶ A continuous infusion of the chelating agent ethylene glycol-bis(2-aminoethylether)- N,N' -tetraacetic acid (EGTA) was used to produce hypocalcemia. Over the 2 hours of observation, a progressive reduction in diaphragmatic force production paralleled the progressive reduction in ionized serum calcium.

Hypomagnesemia, a common occurrence in the ICU, can also cause respiratory muscle weakness. Dhingra and colleagues¹⁴⁷ reported improvements in maximal inspiratory and expiratory pressures in 17 hypomagnesemic patients following magnesium replacement therapy but not following placebo therapy.

Severe hypokalemia can be caused by several disorders including posthypercapnic alkalosis, renal tubular acidosis, primary hyperaldosteronism, gastrointestinal potassium losses, use of diuretics, thyrotoxic periodic paralysis, familial hypokalemic paralysis, β_2 -adrenergic agonists, and licorice ingestion. When the serum potassium concentration decreases below 2.0 to 2.5 mEq/L, patients may develop muscular weakness (including respiratory muscle weakness) and arrhythmias. Hypokalemia-associated respiratory muscle weakness can result in respiratory failure and death.¹⁴⁸

Decreased Oxygen Delivery

Laboratory animals with cardiogenic shock¹⁴⁹ or with septic shock^{86,150} die of respiratory failure. Death is not caused by pulmonary disease per se but by an inability of the respiratory muscles to maintain adequate ventilation. This inability to maintain adequate ventilation is caused by insufficient oxygen delivery to the respiratory muscles.⁴

Whether the decrease in oxygen delivery to the respiratory muscles—or the respiratory centers—during shock is sufficient to decrease respiratory muscle performance and cause hypoventilation in patients, although likely,¹⁵¹ remains to be determined. A nonrandomized study by Kontoyannis and coworkers¹⁵² in 28 patients with cardiogenic shock provides support for the view that hemodynamic instability could decrease respiratory muscle performance in patients with shock. Compared with nonventilated patients, ventilated patients were weaned from an intra-aortic balloon pump more often, and their survival was greater.¹⁵² These

results are in line with the observation of Viires and associates¹⁵³ who reported decreased metabolic requirements of the diaphragm following institution of mechanical ventilation in dogs with cardiogenic shock.

Some hemodynamic situations that are less extreme than shock could still affect respiratory muscle performance, including failed attempts of spontaneous respiration during weaning from mechanical ventilation. Jubran and colleagues¹⁵⁴ investigated the importance of hemodynamic performance in determining weaning outcome in 8 ventilator-supported patients who failed a trial of spontaneous breathing and 11 patients who tolerated a trial and were successfully extubated. Immediately before the trial, mixed oxygen venous saturation was not different between the two groups. Mixed venous oxygen saturation progressively decreased over the course of the trial in the failure group, whereas it remained unchanged in the success group (Fig. 40.16, upper panel). Although the calculated oxygen demand was similar in the two groups, the manner in which it was met differed between them. In the success group, oxygen transport increased, mainly resulting from an increase in cardiac index; in the failure group, the increase in demand was met by an increase in oxygen extraction, resulting in a decrease in mixed venous oxygen saturation (Fig. 40.16, lower panel). Although increased, the oxygen extraction ratio at the end of the trial in the failure group was close to the ratio reported to signify the onset of anaerobic metabolism (0.60)¹⁵⁵ in only two patients, who had ratios of 0.50 and 0.56, respectively. The ability of the failure group to deal with respiratory muscle energy demands through aerobic pathways is probably related to the capacity of the diaphragm to achieve higher blood flow than most other skeletal muscles.¹⁵⁶ During loading, the diaphragm rapidly increases oxygen extraction to a plateau of about 55% to 65%; further increases in oxygen demand are achieved by increases in blood flow.^{157,158} The diaphragmatic musculature appears to be extremely resistant to hypoxic stress, and animals can maintain a ventilation that is sufficient to avoid hypercapnia until phrenic vein P_{O_2} falls to 12 mm Hg.¹⁵⁶ Likewise, investigators have found that an oxygen tension of about 10 mm Hg in the phrenic vein is the threshold associated with the onset of diaphragmatic lactate production¹⁵⁹ and the development of fatigue.¹⁶⁰ The lowest mixed venous oxygen tension recorded by Jubran and colleagues¹⁵⁴ was 26 mm Hg, which is above the threshold for onset of diaphragmatic lactate production. This association needs to be interpreted with caution, however, because mixed venous blood contains effluents from many tissue beds other than the diaphragm. The investigation of Jubran and colleagues¹⁵⁴ is the first documentation that, when challenged by an increase in mechanical load,⁷ the respiratory muscles of critically ill patients do not appear to switch from aerobic to anaerobic metabolism.

High variability in hemodynamic response during failure to wean has been reported by Zakyntinos and coworkers.¹⁴ Similar to Jubran and colleagues,¹⁵⁴ Zakyntinos and coworkers¹⁴ recorded a decrease in mixed venous oxygen saturation and an increase in oxygen consumption (met mainly by an increase in oxygen extraction) in 9 of 18 weaning failure patients. In the remaining 9 failures, however, mixed venous oxygen saturation and oxygen consumption were not affected by the weaning trial. It is unclear

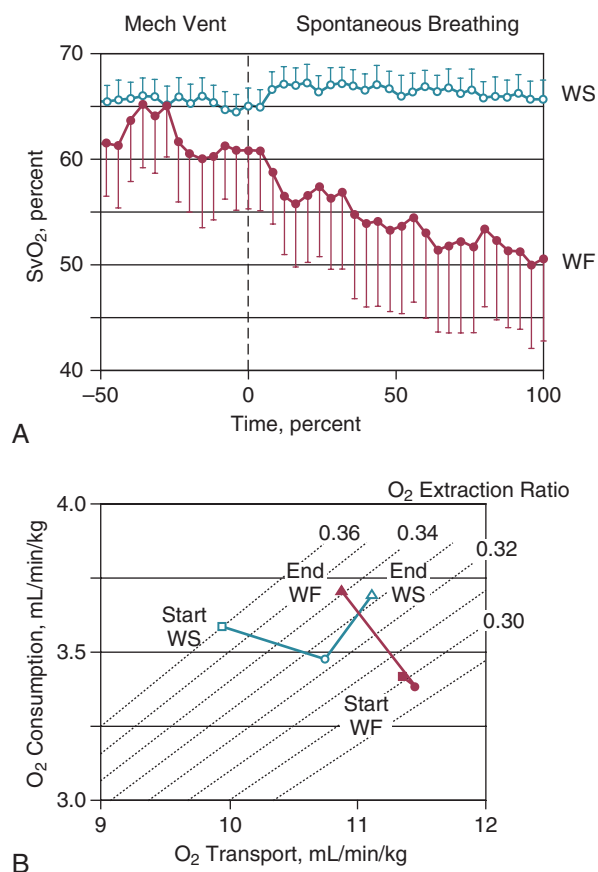

Figure 40.16 A, Mixed venous oxygen saturation (SvO_2) during mechanical ventilation and a trial of spontaneous breathing in 11 weaning success patients (WS, open symbols) and in 8 weaning failure patients (WF, closed symbols). During mechanical ventilation, SvO_2 was similar in the two groups ($p = 0.28$). Between the onset (dashed line) and the end of the trial, SvO_2 decreased in the failure group ($p < 0.01$), whereas it remained unchanged in the success group ($p = 0.48$). Over the course of the trial, SvO_2 was lower in the failure group than in the success group ($p < 0.02$). Bars indicate SE (standard error). B, Oxygen transport, oxygen consumption, and isopleths of oxygen extraction ratio in the success (WS, open symbols) and failure (WF, closed symbols) groups during mechanical ventilation (squares) and at the onset (circles) and end (triangles) of a spontaneous breathing trial. See text for details. (Modified from Jubran A, Martho M, Dries E, et al: Continuous recordings of mixed venous oxygen saturation during weaning from mechanical ventilation and the ramifications thereof. *Am J Respir Crit Care Med* 1998;158:1763.)

whether the absent interaction between weaning failure and oxygen consumption was due to depression of the respiratory centers, limited capacity to extract oxygen, or limited cardiac reserve.¹⁶¹

Medications

Weakness can result from medications that have a direct myotoxic effect, such as blockade of myocyte glycoprotein synthesis and electron transport caused by inhibitors of the hydroxymethylglutaryl coenzyme A reductase or nucleoside analogs used in patients with human immunodeficiency virus.¹⁶²⁻¹⁶⁵ Weakness can also result with neuromuscular blocking agents and aminoglycosides, which interfere with neuromuscular transmission.^{166,167}

Paralysis, including the respiratory muscles, can persist after discontinuation of neuromuscular blocking agents.¹⁶⁷⁻¹⁶⁹ Prolonged neuromuscular blockade has been defined as 2,¹⁶⁷ 4,¹⁶⁹ or 6 hours¹⁶⁸ of paralysis after discontinuation of neuromuscular blocking agents. Prolonged blockade is estimated to occur in 12% to 44% of patients receiving pancuronium or vecuronium for 1 or more days.¹⁶⁷⁻¹⁶⁹ The risk with vecuronium is increased in patients with renal failure.^{167,169} Accumulation of metabolites of the neuromuscular blocking agents is responsible for the prolonged blockade.¹⁶⁷ Recovery from prolonged neuromuscular blockade begins within 2 days of the last dose,^{167,168} and this contrasts with the prolonged course of critical illness myopathy or neuropathy.^{112,120,170,171} Train-of-four monitoring of the dose of a neuromuscular blocking agent with a peripheral nerve stimulator may hasten recovery.¹⁶⁹

LIMITATIONS IN THE CURRENT CLASSIFICATION OF RESPIRATORY MUSCLE WEAKNESS

When one is studying respiratory muscle weakness leading to hypoventilation in critically ill patients it is necessary to bear in mind the current limited understanding of these conditions, as follows:

1. The distinction between preexisting conditions and new-onset conditions can be arbitrary.
2. Conditions that are preexisting (malnutrition and hyperinflation) can worsen during the course of an unrelated critical illness.
3. The nosologic designation is often unsatisfactory—see the nebulous distinction between ICU-acquired paresis and sepsis-associated myopathy or between ICU-acquired paresis and ventilator-associated respiratory muscle dysfunction.
4. Conditions in which respiratory muscle weakness is associated with muscle damage can display also some degree of muscle atrophy—see diaphragmatic atrophy in cases of ventilator-associated respiratory muscle dysfunction.
5. Laboratory specificity to differentiate the various conditions causing weakness in the ICU is limited.
6. In any given patient more than one mechanism may be responsible for respiratory muscle weakness.
7. Respiratory muscle weakness can be combined with depressed drive—for example, in the setting of hypercapnia-induced hypoventilation.

RESPIRATORY MUSCLE FATIGUE

Contractile fatigue occurs when a sufficiently large respiratory load is applied over a sufficiently long period.^{15,172-180} Contractile fatigue can be brief or prolonged. Short-lasting fatigue results from accumulation of inorganic phosphate,^{135,181,182} failure of the membrane electrical potential to propagate beyond T tubules,¹⁸³ and to a much lesser extent intramuscular acidosis.¹⁸⁴⁻¹⁸⁶ Short-lasting fatigue appears to have a protective function, because it can prevent injury to the sarcolemma caused by forceful muscle contractions.¹⁸⁷ Long-lasting fatigue¹⁷³ is consistent with the development of, and recovery from, muscle injury (Fig. 40.17).^{187,188}

Whether critically ill patients develop short-lasting or long-lasting contractile fatigue of the respiratory muscles is not clear. Patients who fail a trial of weaning from mechanical ventilation are at particular risk of developing fatigue because they experience marked increases in respiratory load.^{7,11,33} The addition of a new injury to the respiratory muscles (secondary to the development of contractile fatigue) might be the ultimate determinant of whether or not some patients are ever successfully weaned. Circumstantial evidence of contractile fatigue in patients experiencing respiratory distress has been reported.^{7,189-191} Because of technical limitations,¹⁸⁹⁻¹⁹¹ these early data did not provide proof of contractile fatigue.^{10,192}

The most direct method for detecting fatigue in patients is to measure the transdiaphragmatic pressure (Pdi) elicited by phrenic nerve stimulation over time (see Fig. 40.2).^{15,173}

Figure 40.17 Electron micrographs of longitudinal sections from the costal diaphragm of a healthy control hamster (*left panel*) and a hamster exposed to 6 days of resistive loading (*right panel*). The left panel shows normal sarcomeres with distinct A-bands, I-bands, Z-bands, and M-lines that are aligned between adjacent myofibrils. The right panel shows load-induced damage recognizable by Z-band streaming (*arrow*) and disruption of sarcomeric structure (*right section of right panel*) with loss of distinct A-bands and I-bands. Z-band streaming is attributed to a loss of cytoskeletal protein elements such as desmin, α -actinin, and vimentin. Magnification for both micrographs: $\times 16,500$. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48. Electron micrographs provided by Drs. David C. Walker and Darlene W. Reid, University of British Columbia, Vancouver, Canada.)

When employing this technique in critically ill patients, it is especially challenging to ensure that successive stimulations are all generated at the same end-expiratory lung volume, to ensure a constant degree of neural depolarization by the stimulator, and ensure that twitch potentiation (the transient increase in pressure that occurs with a recent forceful contraction) does not occur.^{15,173} Controlling for these factors, Laghi and associates¹³ studied 11 weaning-failure patients and 8 weaning-success patients before and after a T-tube trial. Twitch Pdi was 8.9 ± 2.2 H₂O before and 9.4 ± 2.4 H₂O after the trial in the weaning-failure patients (Fig. 40.18). The respective values in the weaning-success patients were 10.3 ± 1.5 and 11.2 ± 1.8 cm H₂O. Not a single patient developed a decrease in twitch Pdi. The absence of fatigue was surprising because 7 of the 9 weaning-failure patients had a tension-time index (the product of two fractions: [mean pressure per breath/maximum transdiaphragmatic pressure] \times [inspiratory time/total time of respiratory cycle]) above the threshold reported to lead to task failure and fatigue (0.15).¹⁹³

One of the most likely reasons that patients did not develop fatigue is that physicians reinstituted mechanical ventilation before there was enough time for its development. The relationship between tension-time index and

the length of time that a load can be sustained until task failure follows an inverse-power function. Bellemare and Grassino¹⁹³ expressed the relationship as follows:

$$\text{time to task failure} = 0.1 (\text{tension} - \text{time index})^{-3.6}$$

The increase in tension-time index over the course of the weaning trial¹³ and predicted time to task failure¹⁹³ are shown in Figure 40.19. At the point that the physician reinstituted mechanical ventilation, patients were predicted to be an average of 13 minutes away from task failure. Moreover, the time to task failure was underestimated because diaphragmatic recruitment during maximal voluntary contractions was incomplete (Fig. 40.20).¹³ In other words, patients display clinical manifestations of severe respiratory distress for a substantial time before they would develop fatigue. In an ICU setting, these clinical signs will lead attendants to reinstitute mechanical ventilation before fatigue has time to develop. Other factors that might have protected the respiratory muscles from contractile fatigue include development of dynamic hyperinflation (susceptibility to fatigue is greater when fatiguing protocols are conducted at optimal muscle length rather than when a muscle is shortened)¹⁹⁴ and activation of extradiaphragmatic muscles of respiration.¹⁹⁵

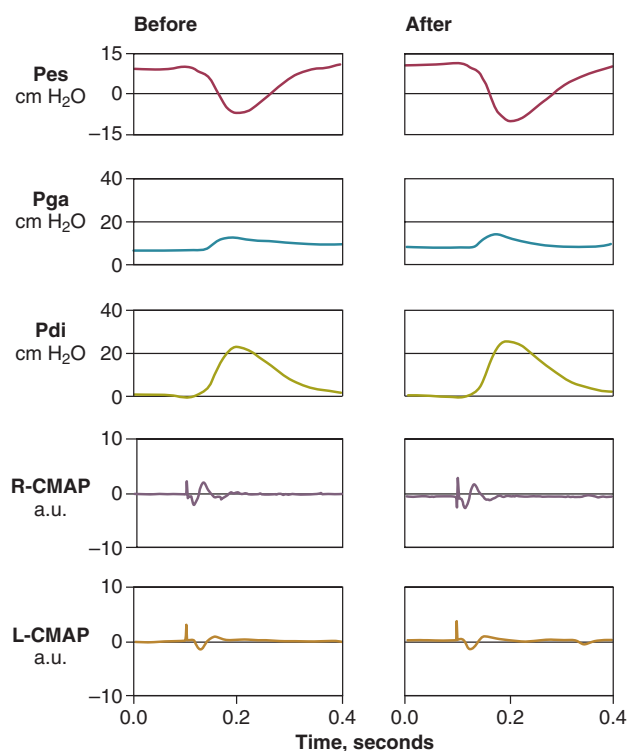

Figure 40.18 Esophageal pressure (Pes), gastric pressure (Pga), transdiaphragmatic pressure (Pdi), and compound motor action potentials (CMAP) of the right and left hemidiaphragms after phrenic nerve stimulation before (*left*) and after (*right*) a failed trial of weaning. The end-expiratory value of Pes and the amplitude of the right and left CMAPs were the same before and after the trial, indicating that the stimulations were delivered at the same lung volume and that the stimulations achieved the same extent of diaphragmatic recruitment. The amplitude of twitch Pdi elicited by phrenic nerve stimulation was equivalent before and after weaning. (From Laghi F, Cattapan SE, Jubran A, et al: Is weaning failure caused by low-frequency fatigue of the diaphragm? *Am J Respir Crit Care Med* 2003;167:120.)

Figure 40.19 The interrelationship between the duration of a spontaneous breathing trial, tension-time index of the diaphragm, and predicted time to task failure in nine patients who failed a trial of weaning from mechanical ventilation. The patients breathed spontaneously for an average of 44 minutes before a physician terminated the trial. At the start of the trial, tension-time index was 0.17, and the formula of Bellemare and Grassino¹⁹³ (see text for details) predicted that patients could sustain spontaneous breathing for another 59 minutes before developing task failure. As the trial progressed, tension-time index increased and predicted time to the development of task failure decreased. At the end of the trial, tension-time index reached 0.26; that patients were predicted to sustain spontaneous breathing for another 13 minutes before developing task failure clarifies why patients did not develop a decrease in diaphragmatic twitch pressure. In other words, physicians interrupted the trial based on clinical manifestations of respiratory distress before patients had sufficient time to develop contractile fatigue. (From Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48.)

Figure 40.20 Continuous recordings of airway pressure and trans-diaphragmatic pressure during airway occlusion in a patient with chronic obstructive pulmonary disease after an unsuccessful trial of spontaneous breathing. Phrenic nerve stimulation (arrow) during the maximal inspiratory effort resulted in a detectable superimposed twitch. That a twitch could be superimposed during the maximal effort indicates that diaphragmatic activation was incomplete.

Studies in animals^{184,196-198} support the finding that patients do not develop long-lasting contractile fatigue of the respiratory muscles. Inspiratory loading in animals causes respiratory failure and acidosis before force output decreases or substrate is depleted in the diaphragm,^{184,196-198} suggesting that central¹⁹⁹ and reflex mechanisms^{200,201} affect the breathing pattern¹⁸⁵ and α -motor neuron firing rates²⁰² in response to loading. Two neural pathways may convey information from the respiratory muscles to the central nervous system.^{203,204} One pathway transmits information from mechanoreceptors (Golgi tendon organs and muscle spindles)^{200,205} in the dorsal column, relaying it to the brainstem and thalamus, before reaching the sensorimotor cortex.²⁰⁶ This pathway may participate in proprioceptive control of the respiratory muscles, integrating movements originating in the motor cortex.¹⁹⁹ The second pathway consists of vagal¹⁹⁸ and possibly phrenic nerve afferents (group IV phrenic afferent fibers)²⁰⁰ that reach the amygdala after relaying in the brainstem and then projecting to the mesocortex (cingulate gyrus). This pathway may deal with respiratory nociception,^{199,207} such as dyspnea (through the relay in the amygdala),²⁰⁸ and with the ventilatory response to carbon dioxide (through the relay in the brainstem, ventral cerebellum, and limbic system).^{199,207,209} In addition to these two pathways projecting to the central nervous system, there is evidence for the existence of a spinal pathway responsible for phrenic-to-phrenic reflex inhibition.²⁰¹ An increase in carbon dioxide during loading may also protect the respiratory muscles by decreasing reactive oxygen species production.²¹⁰

Resistive breathing causes hypercapnia without affecting diaphragmatic force output or aerobic metabolism (assessed by ³¹P nuclear magnetic resonance spectroscopy) in spontaneously breathing piglets.^{7,185,211} The hypoxia combined with resistive breathing caused a decrease in diaphragmatic force and inadequate oxidative metabolism, as reflected by accumulation of inorganic phosphorus and decreased phosphocreatine.¹⁸⁵ Force output and oxidative metabolism returned to baseline values with normoxia despite persistent loading.¹⁸⁵ The investigators speculated that

loading produces a decrease in central activation (to the point of ventilatory failure), which decreases metabolic demands and prevents peripheral fatigue; additional stress of hypoxia may overwhelm this defense mechanism and cause peripheral fatigue.¹⁸⁵ Hypoxemia can also induce degradation of myofibrillar proteins.²¹²

Hypoxia impairs the respiratory centers at a higher oxygen tension than it impairs the respiratory muscles,^{160,213} making it difficult to decipher the effects of hypoxemia on the respiratory muscles. Animals develop severe alveolar hypoventilation and respiratory arrest before the tension-generating ability of the diaphragm has begun to decrease.^{160,213} As previously stated, it is unknown whether, in patients with shock,¹⁵¹ decreases in oxygen delivery to the respiratory muscles^{154,214} or respiratory centers can be sufficient to cause hypoventilation.

INCREASED LOAD

Increased respiratory load can result from increased mechanical load and increased ventilatory requirements.

INCREASED MECHANICAL LOAD

Patients in acute respiratory failure usually experience an increased mechanical load.* The patients typically have a 30% to 50% greater inspiratory resistance,^{7,13,33} 100% greater dynamic elastance,^{7,11} and 100% to 200% greater intrinsic positive end-expiratory pressure (PEEP)^{7,11,13} than do similar patients who are not in acute respiratory failure. Inspiratory effort—quantified by calculation of the pressure time product of the inspiratory muscles—is almost equally divided in offsetting intrinsic PEEP, elastic recoil, and inspiratory resistance (Fig. 40.21).^{7,211} Abnormal mechanics arise from bronchoconstriction, bronchial edema, pulmonary edema,⁷ and lung inflammation.^{215,216} Rapid shallow breathing can aggravate the abnormalities in lung elastance, intrinsic PEEP, and carbon dioxide clearance.^{7,33} Expiratory muscle recruitment can also increase intrinsic PEEP and breathing effort.²¹⁸ In some patients, increased mechanical load results from upper airway obstruction. The upper airway, which encompasses the passage between the nares and carina, can be obstructed by functional or anatomic causes. Among the first are vocal cord paralysis and laryngospasm. Among the second are trauma, burn, infections, foreign bodies, and tumors. Functional and anatomic obstruction can occur postoperatively in patients with redundant pharyngeal soft tissue (sleep apnea) and loss of muscle tone related to postanesthetic state.¹ Upper airway obstruction is one of the most urgent and potentially lethal medical emergencies.¹ Complete airway obstruction lasting for as little as 4 to 6 minutes can cause irreversible brain damage.¹

INCREASED VENTILATORY REQUIREMENTS

Increased ventilatory requirements can result from increased carbon dioxide production, increased dead space ventilation, and elevated respiratory drive. Carbon dioxide

*See References 7, 11, 13, 33, 211, and 215-217.

Figure 40.21 Quantification of inspiratory effort with pressure-time product of the inspiratory muscles. Flow (inspiration upward) and pressure tracings during spontaneous breathing. Recoil pressures of the chest wall (CW) and lung are calculated from dynamic elastances of the chest wall and lung, respectively, and lung volume. Upper bound inspiratory pressure-time product (PTP) is calculated using the integral of the difference between esophageal pressure (P_{es}) and upper bound CW recoil pressure from the onset of the rapid decrease in P_{es} to the transition from inspiratory to expiratory flow. The component of PTP due to intrinsic positive end-expiratory pressure (PEEP_i) is computed using the integral of the difference between the upper and lower bounds of CW recoil pressure from the onset of rapid decrease in P_{es} to the transition from inspiratory to expiratory flow. The component of PTP due to non-PEEP_i elastance is computed using the integral of the difference between lung recoil pressure and lower bound CW recoil pressure from the onset of inspiratory flow to the moment of transition from inspiratory to expiratory flow. The resistive fraction of PTP is computed using the integral of the difference between P_{es} and lung recoil pressure. The vertical interrupted lines represent points for zero flow. (From Jubran A, Tobin MJ: Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1997;155:906.)

production can increase as a result of sepsis,⁸⁶ fever, shivering, drugs (salicylates), lipogenesis,^{219,220} and a shift in utilization of fuels from lipids ($RQ = 0.7$) to carbohydrates ($RQ = 1.0$).²²¹ An increase in carbon dioxide production can only be a contributory factor and not a sole cause of hypercapnic respiratory failure.³

The ratio of dead space to tidal volume is normally 0.30. The ratio increases up to 0.65 in patients with severe COPD,²²² ARDS,²²³ and other severe lung diseases.³ Patients can compensate for such an increase in dead space by doubling minute ventilation.³ Such an increase in minute ventilation poses a minor challenge when respiratory mechanics and respiratory muscles are normal; for example, hypercapnia is uncommon with pulmonary vascular disease.³ Accordingly, an increase in dead space ventilation should never be considered the primary mechanism responsible for hypercapnic respiratory failure unless there is a concurrent abnormality in the control of breathing, or in the mechanical load of the respiratory muscles or in their contractile performance.³

Stimulation of pulmonary irritant or J receptors, neurologic lesions, sepsis, and toxins can inappropriately increase respiratory drive. Whether an inappropriately heightened drive places sufficient stress on the respiratory muscle to cause respiratory muscle fatigue and, consequently, hypoventilation remains to be determined.

HYPERCAPNIA-INDUCED HYPOVENTILATION

Severe hypercapnia depresses the central nervous system and decreases respiratory motor output.²²⁰ A vicious circle can arise, whereby hypercapnia causes depressed drive leading to more hypercapnia.^{224,225} The possibility of hypercapnia-induced hypoventilation is supported by reports of successful resolution of hypercapnic respiratory failure in some patients following short-term infusion of the respiratory stimulant, doxapram.^{224,225}

SUMMARY

A relative or absolute decrease in respiratory muscle output is responsible for alveolar hypoventilation and hypercapnic respiratory failure. The number of distinct clinical entities that result in hypercapnia is vast and often more than one disease process may coexist—e.g., hyperinflation-associated respiratory muscle weakness and ventilation-perfusion inequality in patients with COPD. The relative or absolute decrease in respiratory muscle output in patients with hypercapnia may stem from a decrease in respiratory drive, excess mechanical load on the respiratory muscles, and respiratory muscle weakness (see Fig. 40.1). Whether respiratory muscle fatigue is responsible for hypercapnic respiratory failure is an important issue that has yet to be resolved.

KEY POINTS

- Hypercapnia is synonymous with alveolar hypoventilation (for the patient's level of carbon dioxide production).
- A relative or absolute decrease in respiratory muscle output is responsible for alveolar hypoventilation.
- Isolated impairments in gas exchange usually do not cause hypercapnia.
- When gas exchange is impaired the magnitude of neuromuscular impairment or increased respiratory load conducive to hypercapnia can be less than the corresponding derangements when gas exchange is intact.
- Respiratory drive is elevated in many patients with acute ventilatory failure. This finding does not necessarily exclude the possibility that during episodes of ventilatory failure the central nervous system is not fully recruiting the respiratory muscles and may be contributing to CO₂ retention.

KEY POINTS (Continued)

- In critically ill patients, respiratory muscle weakness is probably responsible for a large number of cases of alveolar hypoventilation.
- Metabolic disturbances such as hypophosphatemia, hypomagnesemia, hypokalemia, and hypocalcemia can cause respiratory muscle weakness.
- Hyperinflation places the respiratory muscles in a mechanical disadvantage to generate the driving pressure of the respiratory system.
- Hyperinflation can occur during episodes of respiratory distress even in patients without history of airway disease (e.g., asthma or COPD).
- The role of respiratory muscle fatigue in causing hypercapnic respiratory failure remains to be determined.
- Severe hypercapnia can in itself be conducive to alveolar hypoventilation by depressing respiratory drive.
- It is still unclear whether respiratory or metabolic acidosis has a clinically relevant direct effect on respiratory muscle contractility.

SECRETION CLEARANCE

INTRODUCTION

An estimated 20% of respiratory failure is a result of nonpulmonary causes such as disorders that affect the upper airway, chest wall, muscles of respiration, and nervous system. Hypoventilation is the primary pathophysiologic etiology of all of these disorders.¹

HYPOVENTILATION

PATHOPHYSIOLOGY (FIG. 41.1)

Hypoventilation is defined as alveolar ventilation that is inappropriately low for metabolic demands. Alveolar (A) and arterial (a) P_{aCO_2} are elevated. Arterial pressure is decreased. Alveolar hypoventilation exists when arterial P_{CO_2} increases above the normal range of 37 to 43 mm Hg.²⁻⁷

Hypoventilation is associated with arterial hypoxemia (when breathing room air oxygen) and a raised arterial P_{CO_2} . The rise in P_{aCO_2} as a result of hypoventilation can be calculated using the *alveolar ventilation equation*.⁸ In a single-compartment lung model, alveolar P_{CO_2} and P_{O_2} are inversely related according to the alveolar air equation. An increase in alveolar P_{CO_2} is associated with an obligatory fall in alveolar P_{O_2} . During hypercapnia, the alveolar minus arterial $P(A - a)O_2$ difference predicted by this model (while

breathing room air) is “normal.” Regarding the combination of hypercapnia and a normal $P(A - a)O_2$ difference as a requirement to diagnose nonpulmonary disorders associated with hypoventilation is common clinical practice. However, these disorders are also commonly complicated by microatelectasis, retention of secretions, and bronchopneumonia, which cause abnormal ventilation/perfusion inequality and increase the $P(A - a)O_2$ difference. Conversely, the $P(A - a)O_2$ difference has been shown to be an unreliable index of abnormal gas exchange in the presence of substantial hypercapnia. For these reasons, a normal $P(A - a)O_2$ difference is not helpful in differentiating pulmonary from nonpulmonary causes of respiratory failure. The alveolar partial pressure of oxygen is calculated with the formula:

$$PAO_2 = PIO_2 - PaCO_2 \left(FIO_2 + \frac{1 - FIO_2}{R} \right)$$

where FIO_2 is the inspired oxygen fraction (0.21 in all calculations) in the dry gas, PIO_2 is the inspired P_{O_2} , and R is the respiratory exchange ratio (assumed to be 0.8). In other words, the flow of CO_2 molecules across the alveolar membrane per minute is divided by the flow of O_2 molecules across the membrane per minute. $PaCO_2$ is the ideal alveolar carbon dioxide tension.

This important equation indicates that the level of PCO_2 in alveolar gas and in arterial blood is inversely related to the alveolar ventilation.

This is true only if a steady state of alveolar ventilation and carbon dioxide production rate exists. In clinical

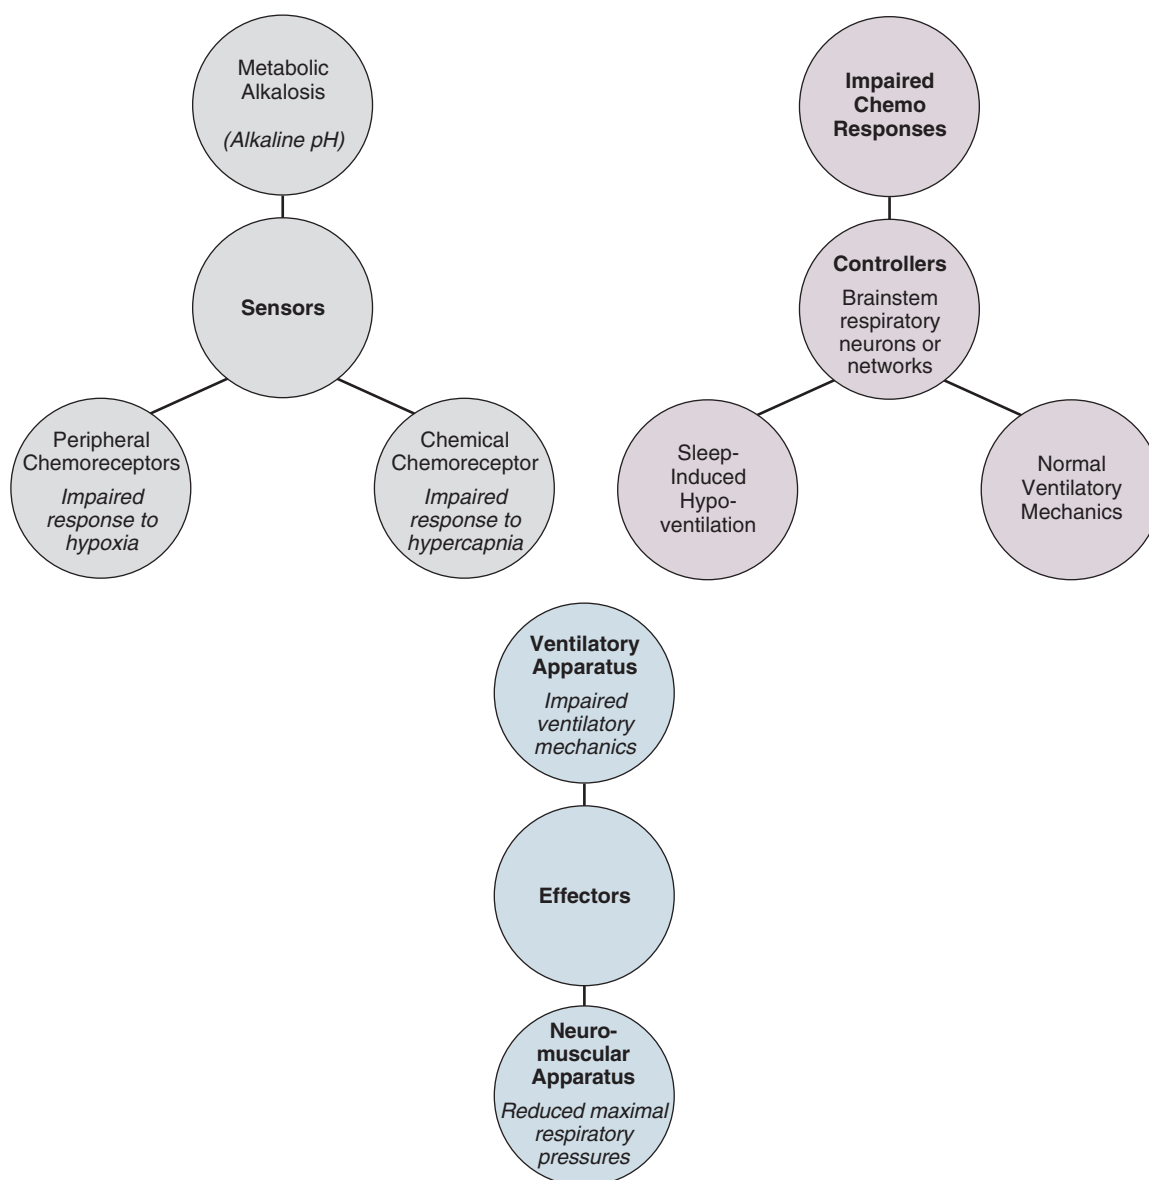

Figure 41.1 Mechanisms underlying chronic alveolar hypoventilation.

practice it is common to consider the combination of hypercapnia and a normal $P(A-a)O_2$ difference as a requirement to diagnose nonpulmonary disorders associated with hypoventilation.⁹ However, hypoventilation-induced atelectasis causing abnormal gas exchange will result in an increase in $P(A-a)O_2$ difference.¹⁰ In the presence of substantial hypercapnia, an abnormal alveolar-to-arterial oxygen difference may not rule out a nonpulmonary cause of hypoventilation.

MECHANISMS UNDERLYING CHRONIC ALVEOLAR HYPOVENTILATION (SEE FIG. 41.1)

Defects in the metabolic control system result in hypoventilation when abnormalities in blood gases and cerebral

acid-base status are not sensed or if sensed do not produce an appropriate change in motor output of the medullary respiratory neurons. Patients with such defects fail to breathe normally in response to metabolic respiratory stimuli, but because the behavioral control system, respiratory motor pathways, and ventilatory apparatus are intact, they are capable of voluntarily driving respiration. As a result, patients with defects in the metabolic control system typically demonstrate normal ventilatory mechanics, but they have impaired responses to metabolic respiratory stimuli and often hypoventilate severely during sleep, when ventilation is critically dependent on the metabolic control system.^{1,3,11-17} As a result of chronic hypoventilation, these patients have a primary respiratory acidosis leading to a secondary increase in extracellular bicarbonate ion concentration.^{18,19}

In contrast, patients with a primary metabolic alkalosis may develop secondary hypoventilation as a compensatory

response. This type of hypoventilation represents not a defect in respiratory control but rather an appropriate response of the metabolic control system to a disturbance in acid-base status. It is said that patients with metabolic alkalosis “shouldn’t” breathe, in contrast to those with control defects, who “won’t” breathe, and those with mechanical defects, who “can’t” breathe. However, the degree of hypoventilation that develops in response to metabolic alkalosis depends on several factors, including associated electrolyte disturbances and the sensitivity of the peripheral chemoreceptors to the accompanying hypoxemia.^{19,20} Therefore, patients with weak hypoxic responsiveness tend to hypoventilate more than do patients with brisk hypoxic responsiveness.

Chronic hypoventilation resulting from defects in effector elements of the respiratory system represents disturbances of ventilatory motor and mechanical function, and these defects do not in themselves mean that the metabolic control system is defective. Because the same effector elements also serve the behavioral control system, these patients are usually unable to breathe normally even when consciously attempting to do so. Hence, such defects are characterized either by reductions in the maximum inspiratory pressures that can be generated voluntarily or by impairment of lung volumes and flow rates.²¹ In the presence of such neural or mechanical defects, coexisting disturbances in respiratory control are often difficult to identify because the neuromuscular or mechanical defect may preclude normal responses to chemical respiratory stimuli even when the control system is intact.¹

ETIOLOGIC CLASSIFICATION

Plum and Leigh^{22,23} described nonrespiratory causes of respiratory failure. Causes of hypoventilation include depression of the respiratory center by drugs such as morphine derivatives and barbiturates; diseases of the brainstem such as encephalitis; abnormalities of the spinal cord conducting pathways such as high cervical dislocation; anterior horn cell diseases including poliomyelitis that affect the phrenic nerves or supplying intercostal muscles; diseases of nerves to respiratory muscles (e.g., Guillain-Barré syndrome); diseases of the myoneural junction such as myasthenia gravis; diseases of the respiratory muscles themselves such as progressive muscular dystrophy; thoracic cage abnormalities (e.g., crushed chest); upper airway obstruction (e.g., thymoma); hypoventilation associated with extreme obesity (Pickwickian syndrome); and other miscellaneous causes such as metabolic alkalosis and idiopathic states.² In all these conditions the lungs are normal.

RESPIRATORY FAILURE FROM NEUROMUSCULAR DISEASE

Neuromuscular diseases are accompanied by variable degrees of involvement of the muscles of inspiration and expiration. The clinical manifestations reflect the compromise of both muscle groups.²⁴ Disorders of respiratory control and those of peripheral neuromuscular disease are shown in [Tables 41.1](#) and [41.2](#), respectively.

TESTS OF RESPIRATORY MUSCLE STRENGTH

Respiratory muscle weakness is the hallmark of most neuromuscular disease. Simple tests measure maximal inspiratory and expiratory pressures (PI_{max} and PE_{max}). These tests are conducted by measuring airway pressures while requiring the patient to make maximal inspiratory and expiratory efforts against a closed airway at low or high volumes, respectively.²⁵ Respiratory muscle force is dependent on age, sex, and lung volume. PI_{max} and PE_{max} of greater than 60 to 80 cm H₂O exclude significant neuromuscular weakness. Abnormally low values are not diagnostic but indicate a need for further assessment.

The classic example of chronic alveolar hypoventilation secondary to brainstem disease is that seen in bulbar poliomyelitis or encephalitis. Secondary causes of alveolar hypoventilation are usually signified by features of the underlying disease.

TESTS OF RESPIRATORY CONTROL AND DRIVE

If the tests of pulmonary function testing are unremarkable, indicating no parenchymal, neuromuscular, or chest wall disease accounting for the patient’s hypercapnia or abnormal ventilation, tests of respiratory control are indicated.

These tests include measurement of hypoxic and hypercapnic ventilatory responses (because ventilatory response to hypoxia and hypercarbia can be potentially hazardous, O₂ saturation and end tidal CO₂ tension should be monitored); analysis of breathing pattern; mouth occlusive pressure (measurement of maximal pressure generated during the first 0.1 second of normal inspiratory effort when the airway is occluded); and elastic and resistive load testing (by breathing through progressively narrower tubes while the sensation of dyspnea is measured by the Borg scale).

Electromyography permits more direct measurements of respiratory muscle strength. Respiratory muscle fatigue is indicated by paradoxical respirations or *respiratory alternans*. The mechanism consists of intermittent decreases or cessation of the contribution of the diaphragm to the inspiratory effort. It has been assumed that this pattern of muscle recruitment indicates diaphragmatic fatigue.²⁶

CLINICAL RECOGNITION AND MANIFESTATIONS

Alveolar hypoventilation exists when arterial PCO₂ increases above the normal range. In clinically important hypercarbia, PCO₂ typically ranges from 50 to 70 mm Hg. Lethargy, confusion, and a depressed level of consciousness are seen as a result of hypercapnia. An increase in intracranial pressure and cerebral blood flow, as well as a decrease in myocardial contractility, occur.² The oxyhemoglobin dissociation curve shifts to the right, which leads to an increase in the release of oxygen to the tissues.

In the acute form, progressive weakness of respiratory muscles leads to rapid reduction in vital capacity followed by respiratory failure with hypoxemia and hypercarbia. Symptoms are those of acute respiratory failure including dyspnea, tachypnea, and tachycardia. In the chronic form,

Table 41.1 Disorders of Ventilatory Control*

Disorder	Associations	Mechanism
Metabolic alkalosis ⁵⁴	Maintenance of metabolic alkalosis for any length of time means that renal homeostatic mechanisms for HCO ₃ ⁻ excretion have been disrupted.	Impaired autonomic control of ventilation. Voluntary control remains intact.
Ondine's curse ^{55,56} (congenital or acquired central alveolar hypoventilation)	Usually caused by congenital hypoventilation syndrome but can be from surgical incisions into the second cervical segment to relieve intractable pain. ⁵⁷ Can also be seen in medullary infarction in an intermittent form. ⁵⁸⁻⁶⁰	Impaired automatic control of ventilation. Voluntary ventilation remains intact. Classically, the patient "forgets to breathe" when asleep. Patient maintains relatively normal blood gas while awake. ^{3,61}
Carotid body resection ⁶²	Introduced in Japan in the 1940s as a treatment for asthma. ^{63,64} Also seen after bilateral endarterectomy for carotid vascular disease.	Depressed hypoxic ventilatory drive during exercise. Generally eucapnic at rest.
Cheyne-Stokes respiration ^{67,68}	Commonly associated with cardiac disease; can also be seen in neurologic disease sedation, sleep, altitude acclimatization. ⁶⁹	Destruction of peripheral chemoreceptors. ^{65,66} Delay between changes in ventilation and detection of the resulting arterial PCO ₂ by the central chemoreceptors maintains a cyclic pattern of respiration.
Myxedema	In critically ill patients, laboratory differentiation between severe hypothyroidism and the euthyroid-sick syndromes is difficult and may require measurement of free hormone levels.	Respiratory muscle weakness. Depression of ventilatory drive. ⁷⁰⁻⁷²
Starvation	Nutritional intervention can return muscle ventilatory function to normal levels. Furthermore, it seems likely that the ventilatory drive can be influenced by dietary intake of amino acids and glucose.	Decreased ventilatory drive, decreased respiratory muscle function, alterations of lung parenchyma and depressed lung defense mechanisms.
Drug effects	Opiates, barbiturates, benzodiazepines	Should be used judiciously in patients with preexisting hypoventilation.
	Medroxyprogesterone [†]	Increases ventilatory drive in normal males leading to about 5 mm fall in PaCO ₂ .
	Theophylline [†]	Used in obesity hypoventilation syndrome. ⁷³⁻⁷⁵ Increases hypoxic ventilatory response and prevents the fall in hypoxic ventilatory response.
	Acetazolamide [†]	Efficacy and side effects of long-term use are unknown. Small, crossover study reduced central apnea in patients with congestive heart failure. ⁷⁶

[†]Effects used for treatment.

impairment of the respiratory muscles affects mechanical properties of the lungs and chest wall, decreases the ability to clear secretions, and eventually may alter the function of the central respiratory centers. Symptoms include orthopnea, fatigue, disturbed sleep, and hypersomnolence.²⁷

Significant hypoxemia may coexist with chronic hypercapnia or occur with the onset of additional acute pulmonary disorders. The administration of supplemental oxygen is expected to worsen hypercapnia. Major processes that contribute are worsening of ventilation perfusion mismatching caused by an attenuation of hypoxic pulmonary vasoconstriction, a decrease in the binding affinity of hemoglobin for CO₂ (Haldane effect), and a decrease in minute ventilation. Importantly, the clinician must be aware that it is imperative to provide supplemental oxygen to maintain adequate tissue oxygenation. This precaution will avoid

potentially life-threatening consequences; however, in the spontaneously breathing patient, the lowest FIO₂ that produces acceptable oxygenation should be chosen. The major adverse effect seen in patients with hypercapnia with use of supplemental oxygen is an abrupt discontinuation of oxygen leading to hypoxemia.²⁸⁻³⁰

When hypoventilation is not caused by decreased central nervous system drive, neuromuscular weakness, or bellows dysfunction, tachypnea is a relatively early manifestation that can be seen in association with near-normal maximum respiratory pressures.³¹ Orthopnea that develops within seconds of lying down is a classic symptom of patients with diaphragmatic paralysis. The pathophysiology of dyspnea resulting from gravitational influences and the mechanical function of the diaphragm during water immersion, another manifestation of diaphragmatic paralysis, are discussed by

Table 41.2 Disorders of the Peripheral Neuromuscular System*

Site of Disease	Disease	Type of Respiratory Failure
Spinal Cord		
Space-occupying lesions	Syringomyelia Multiple sclerosis ⁷⁷ Mass	Chronic respiratory failure Chronic respiratory failure Chronic respiratory failure
Anterior horn cell lesions	Poliomyelitis ^{5,16,78} Amyotrophic lateral sclerosis	Chronic respiratory failure Chronic respiratory failure
Inhibiting neuronal blockade	Tetanus	Acute respiratory failure
Any level	Traumatic injury	Acute respiratory failure
Motor Nerves		
Peripheral Neuropathy	Phrenic nerve injury ⁵⁴ Beriberi ⁷⁹ Guillain-Barré ⁸⁰ Critical illness polyneuropathy ^{81,82} Lyme disease ⁸³ Diphtheria ⁸⁴	Acute/chronic respiratory failure Chronic respiratory failure Chronic respiratory failure Chronic respiratory failure Chronic respiratory failure Acute respiratory failure
Neuromuscular Junction	Tick paralysis ⁸⁵ Organophosphate poisoning Botulism ⁸⁶ Eaton-Lambert syndrome Myasthenia gravis ^{5,31}	Acute respiratory failure Acute respiratory failure Acute respiratory failure Acute/chronic respiratory failure
Muscle Involvement		
Dystrophies	Muscular dystrophy ^{5,31,87-89} Myotonic dystrophy ^{90,91}	Chronic respiratory failure Chronic respiratory failure
Myopathy	Polymyositis, dermatomyositis, and other collagen vascular diseases ⁹² Malnutrition ⁹³ Thyroid, adrenal, pituitary glands Metabolic acid-base, electrolyte ^{4,18-20}	Chronic respiratory failure Chronic respiratory failure Chronic respiratory failure Acute respiratory failure
Disorders of the Chest Wall	Obesity hypoventilation ^{4,94-96} Asphyxiating thoracic dystrophy ⁹⁷ Fibrothorax ⁹⁸ Thoracoplasty ⁹⁸ Ankylosing spondylitis ⁹⁸ Flail chest	Acute/chronic respiratory failure Acute/chronic respiratory failure Acute/chronic respiratory failure Acute/chronic respiratory failure Acute/chronic respiratory failure Acute/chronic respiratory failure

McCool and Mead.³² Normal diaphragm contraction is associated with a downward movement of the diaphragm and outward movement of the abdomen. When subjects with diaphragmatic paralysis are observed in a supine posture, a paradoxical inward motion of the abdomen can be observed during inspiration. Because these patients are unable to develop transdiaphragmatic pressure gradients, the abdominal contents are drawn toward the chest by the inspiratory fall in pleural pressure generated by the accessory muscles of respiration.³³

PATIENT MANAGEMENT

RESPIRATORY FAILURE

Respiratory failure is defined as a failure to maintain adequate gas exchange and is characterized by abnormalities of

arterial blood gas tensions. *Type 1 failure* is defined by a PaO_2 of less than 60 mm Hg with a normal or low PaCO_2 . *Type 2 failure* is defined by a PaO_2 of less than 60 mm Hg and a PaCO_2 of greater than 50 mm Hg. Respiratory failure can be acute, acute on chronic, or chronic. Although not always clear cut, this distinction is important in deciding on the location of patient treatment and the most appropriate treatment strategy, particularly in type 2 respiratory failure:

- *Acute hypercapnic respiratory failure*: the patient will have no, or minor, evidence of preexisting respiratory disease, and arterial blood gas tensions will show a high PaCO_2 , low pH, and normal bicarbonate.
- *Chronic hypercapnic respiratory failure*: evidence of chronic respiratory disease, high PaCO_2 , near normal pH, high bicarbonate.
- *Acute-on-chronic hypercapnic respiratory failure*: an acute deterioration in an individual with significant preexisting

hypercapnic respiratory failure, high Paco_2 , low pH, high bicarbonate.³⁴

ACUTE RESPIRATORY FAILURE CAUSED BY NEUROMUSCULAR DISEASE

Involvement of the inspiratory and expiratory muscle groups in neuromuscular disease occurs to variable degrees.^{24,35} Inspiratory muscle fatigue occurs as muscle weakness progresses or because of excessive ventilatory demands, as in systemic infection. Respiratory rate increases as a usual response to preserve minute ventilation. Work of breathing is increased in tachypnea due to increased dead-space ventilation and by decreased relative time spent in expiration. Blood flow to respiratory muscles is compromised because this occurs primarily during expiration.³⁵ Weakness of inspiratory muscles predisposes to atelectasis because of reduced tidal volume and vital capacity. The elastic recoil of the stretched thoracic and lung tissue provides driving pressure for airflow. Therefore, expiratory muscle weakness has less impact on respiratory ventilation and mechanics. Essential function of the expiratory muscle is that of generation of an effective cough and clearance of secretions.

Respiratory clinical manifestations include tachypnea, abdominal paradox, respiratory alternans, and small tidal volume.

The risk of respiratory failure increases significantly when the vital capacity (VC) falls below 15 mL/kg, particularly if there is a clear downward trend. Serial measurements of vital capacity at the bedside are helpful in this situation.^{36,37} Careful assessments of ability to protect airway, oxygenation, ability to ventilate, and chest radiographs are essential in determining need for assistance with ventilation.³⁸ Ideally, ventilatory support should be initiated in the setting of impending respiratory failure, when there has been a clear downward trend, rather than having to initiate after the development of cardiovascular instability. Noninvasive ventilation or endotracheal intubation with initiation of positive pressure ventilation is indicated at this time. An anticipatory approach avoids risks associated with emergent intubation and minimizes complications.³⁹⁻⁴¹

Supportive care is an important factor. Nutritional support, psychological and emotional support, physical therapy, range of motion exercises to prevent joint malalignment, tendon shortening and skin care to prevent pressure sores, and prevention of thromboembolic disease should be initiated as soon as possible.

NONINVASIVE POSITIVE PRESSURE VENTILATION

In a patient with intact bulbar function, noninvasive ventilation should be the ventilatory support of choice because of its efficacy, convenience, and portability. A progression of underlying disease will ultimately require invasive ventilation.

Noninvasive ventilation (NIV) is widely used for acute and chronic respiratory failure via mask (Figs. 41.8, 41.9, 41.10, and 41.11). If arterial blood gas tensions do not improve, the level of support can be increased. If the aim is to abolish muscle effort completely, there is little to be gained by increasing the level of inspiratory pressure above 20 cm H_2O (chest wall deformity) or 25 cm H_2O (chronic

obstructive pulmonary disease).^{42,43} NIV is widely considered to be an effective treatment in patients with chronic ventilatory failure caused by chest wall deformity and neuromuscular disease.⁴⁴

WHEN TO USE NONINVASIVE VENTILATION IN NONPULMONARY CAUSES OF RESPIRATORY FAILURE⁴⁵

PATIENTS

- Chest wall deformity
- Neuromuscular disorder
- Decompensated obstructive sleep apnea (OSA)

BLOOD GASES

- Respiratory acidosis ($\text{Paco}_2 > 50$ mm Hg, pH < 7.35, or $\text{H}^+ > 45$ nmol/L) that persists despite maximal medical treatment and appropriate controlled oxygen therapy (patients with pH < 7.25 or $\text{H}^+ > 56$ nmol/L respond less well and should be managed in an intensive care unit)
- Low A-a oxygen gradient (patients with severe life-threatening hypoxemia are more appropriately managed by tracheal intubation)

CLINICAL STATE

- Sick but not moribund
- Able to protect airway
- Conscious and cooperative
- Hemodynamically stable
- No excessive respiratory secretions
- Few comorbidities

CONTRAINDICATIONS EXCLUDED

- Facial burns/trauma/recent facial or upper airway surgery
- Vomiting
- Fixed upper airway obstruction
- Undrained pneumothorax

PREMORBID STATE

- Potential for recovery to quality of life acceptable to the patient
- Patient's wishes considered

CONTRAINDICATIONS TO NONINVASIVE VENTILATION³⁴

- Facial trauma/burns
- Recent facial, upper airway, or upper gastrointestinal tract* surgery
- Fixed obstruction of the upper airway
- Inability to protect airway*
- Life-threatening hypoxemia*
- Hemodynamic instability*
- Severe comorbidity*
- Impaired consciousness*
- Confusion/agitation*
- Vomiting

*NIV may be used despite the presence of these contraindications if it is to be the "ceiling" of treatment.

- Bowel obstruction*
- Copious respiratory secretions*
- Focal consolidation on chest radiograph*
- Undrained pneumothorax*

CHRONIC RESPIRATORY FAILURE

Prolonged mechanical ventilation is defined by the Centers for Medicare and Medicaid Services in the United States as greater than 21 days of mechanical ventilation for at least 6 hours per day.⁴⁶ Most patients requiring prolonged mechanical ventilation will have a tracheostomy (Fig. 41.12) placed to facilitate comfort, communication, and chronic ventilator facility or home ventilation placement. Common problems among patients undergoing prolonged mechanical ventilation are similar to those on short-term ventilation including the following:⁴⁷⁻⁵⁰

*NIV may be used despite the presence of these contraindications if it is to be the “ceiling” of treatment.

- Infections (e.g., pneumonia, line sepsis, *Clostridium difficile* colitis)
- Ileus
- Renal failure
- Pneumothorax
- Seizures
- Tracheal bleeding
- Laryngeal edema
- Development of tracheal granulation tissue
- Tracheoesophageal fistula formation
- Loss of airway patency because of unplanned extubation or decannulation

CHRONIC VENTILATORY-ASSIST DEVICES

Methods of chronic mechanical ventilation include noninvasive and invasive techniques (Tables 41.3 and 41.4). Ventilatory-assist devices have been used for chronic respiratory failure for decades. Initially, negative-pressure ventilators were used, but this approach was soon replaced by the

Table 41.3 Ventilatory-Assist Devices*

Mode of Ventilation	Example	Advantages	Disadvantages	Applications
Abdominal displacement	Pneumobelt (Fig. 41.2A through C)	Noninvasive	Requires sitting. Skin abrasions at points of contact.	Diaphragm paralysis or weakness, high cord lesions, mainly for daytime use. Typical settings rate 16-24; pressure 35-50 cm H ₂ O.
		Portable	Upper airway obstruction.	
	Rocking bed (Fig. 41.3)	Simplicity	Not portable.	Diaphragm paralysis or weakness, mainly for nocturnal use. Typical settings 12-16/min.
Diaphragmatic pacing (Fig. 41.4)			Motion sickness.	Intact phrenic nerve and diaphragm muscle; high cord lesion and central hypoventilation.
Expiratory aids ⁹⁹ ; manually assisted coughing (“quad” coughing), cough in-exsufflator percussionator Hayek oscillator (Fig. 41.5) Glossopharyngeal breathing				Peak cough flow augmentation in patients with expiratory muscle weakness.
Negative-pressure ventilation	Pneumosuit (Fig. 41.6)	Portable	Difficulty applying suit. Cumbersome. Upper airway obstruction.	Postpolio and muscular dystrophy patients. Respiratory muscle weakness, but upper airway function is intact. Typical settings: Pressure -20 to -40 cm H ₂ O. ¹⁰¹ Rate 14-18.
	Chest cuirass	Allows speech and feeding Portable	Fitting difficulties. Upper airway obstruction.	Typical settings: Pressure -20 to -40 cm H ₂ O. ¹⁰¹ Rate 14-18.
	Iron lung (Fig. 41.7)	Reliable	Confining. Not portable.	Second line for patients if nasal ventilation fails. Typical settings: Rate 12-14. Pressure -12 to -25 cm H ₂ O.

Table 41.3 Ventilatory-Assist Devices* (Continued)

Mode of Ventilation	Example	Advantages	Disadvantages	Applications
Positive-pressure ventilation			Upper airway obstruction	Mode of first choice. Nasal route preferred, oronasal or mouthpiece if nasal unsuccessful. Typical settings Rate 12-24; inspiratory pressure 10-20 cm H ₂ O Expiratory pressure 12-15 cm H ₂ O.
Volume-cycled	PLV-100 and 102 (Respironics, Inc.) Companion 2801 (Mallinckrodt, Inc.) LP 6 Plus	Allows tidal volume adjustment High/low airway pressure alarms		
Pressure-cycled	LP 10 Quantum PSV BI-PAP S/T KnightStar 335 VPAP Adapt SV (ResMed Inc.)	Apnea alarms Usually used noninvasively Mandatory rate available		Adaptive-servo ¹⁰⁰ ventilator is designed specifically to treat central sleep apnea (CSA) in all its forms. Adapts to the patient's ventilatory needs on a breath-by-breath basis and automatically calculates a target ventilation. Adjusts the pressure support to achieve it.

Table 41.4 Interfaces for Ventilatory-Assist Devices

Mode of Delivery	Example	Advantages	Disadvantages
Noninvasive	Nasal mask (Fig. 41.8)	Avoids tracheostomy complications Less claustrophobia	Mouth leak Patent nares required Nasal bridge ulceration Patient cooperation required
	Nasal pillows (Fig. 41.9) Oronasal mask (Fig. 41.10)	Avoids tracheostomy complications Avoids tracheostomy complications	Mouth leak Poor seal Aspiration risk Cannot speak
	Mouthpiece (Fig. 41.11)	Avoids tracheostomy complications	Increased secretions Cannot speak
Invasive	Tracheostomy (Fig. 41.12)	Allows suctioning	Surgical procedure required

use of volume-cycled ventilation delivered by a tracheostomy. Because this patient population was in a terminal stage without other treatment options, tracheostomy and chronic ventilation became the standard of therapy if the patient wanted to continue aggressive care.

Major ethical considerations surround the institution of chronic ventilatory support.⁵¹ This issue is evolving rapidly

because of the widespread availability of relatively inexpensive technology. Guidelines have been published regarding clinical indications and management strategies for the use of noninvasive positive pressure ventilation, although they are based on inadequate data.^{52,53} The discussion about ventilatory assistance should occur before an emergent setting. Adequate and unbiased information should be given to

Figure 41.2 A-C, Pneumobelt. B, Pneumobelt connected to the Thompson Bantam positive pressure ventilator. The ventilator intermittently inflates a rubber bladder contained within the corset.

patients so that they can make an informed decision. Different ventilatory methods and modes of delivery should be discussed with patients, including the possibility of foregoing any type of mechanical ventilation. Patient and caregiver quality of life and satisfaction have only recently been investigated in this population, and many unanswered questions remain. Management of the terminal phase can also be difficult.

MANAGEMENT OF AIRWAY SECRETION CLEARANCE

An understanding of neuromuscular respiratory pathophysiology and the modes of effective noninvasive cough support is key in the evaluation and management of neuromuscular diseases. A variety of cough-augmentation therapies or a combination of these therapies can be used to support cough.¹⁰² Here are some examples of clearance device categories:

- Manual cough augmentation
- Hyperinflation maneuvers
- Functional electrical and magnetic stimulation
- Mechanical in-exsufflation therapy

KEY POINTS

- A normal $P(A - a)O_2$ difference should not be required as a diagnostic criterion for nonpulmonary causes of respiratory failure.
- The etiologic classification of nonpulmonary disorders causing respiratory failure consists of the following broad categories: disorders of ventilatory control, neuromuscular disorders, disorders of the chest wall, and upper airway obstruction.
- Clinical recognition of these disorders depends on familiarity with the physiologic consequences of chronic hypoxia and hypercapnia, the signs and symptoms of respiratory muscle weakness, and their effects on pulmonary function tests.
- An understanding of neuromuscular respiratory pathophysiology and the modes of effective noninvasive cough support is key in the evaluation and management of neuromuscular diseases.
- The approach to the management of acute respiratory failure does not differ in principle from the approach used for lung diseases.
- Noninvasive nocturnal ventilatory support has gained acceptance as a means of controlling diurnal hypercapnia and providing respiratory muscle rest.

Community-Acquired Pneumonia

Nosocomial Pneumonia

Severe pneumonia with respiratory failure and sepsis is one of the commonest indications necessitating intensive care unit (ICU) admission. Pneumonia along with influenza was the eighth leading cause of death in 2009 alone. Pneumonia patients are managed in the ICU when severe forms of community-acquired pneumonia (CAP) are present or when a hospitalized patient develops life-threatening nosocomial pneumonia. Pneumonia patients admitted to the ICU usually have more severe disease, other comorbid medical conditions, and much higher mortality rate compared to the patients admitted to the wards.¹

The incidence of pneumonia in hospitalized patients is directly related to the degree of underlying systemic illness and number of days on the ventilator.² The elderly account for a disproportionate number of critically ill patients with all forms of pneumonia, often because they commonly have comorbid illness, which predisposes them to more severe forms of infection, and their short- and long-term mortality rates are higher than those of younger patients.³ Also,

hospitalized patients receive therapeutic interventions that predispose them to pneumonia such as endotracheal intubation, nasogastric feeding, antibiotic therapy, and use of immunomodulatory medications. In 2005, there were more than 60,000 deaths in persons aged 15 years or older related to CAP in the United States.⁴ The mortality rate from severe CAP is over 30% in patients admitted to the ICU.⁵ Critically ill patients who develop ventilator-associated pneumonia (VAP) have a higher mortality rate compared with similar patients without VAP and incur USD \$10,019 or more in additional hospital costs.⁶

With newer guidelines, there has been an emphasis on identifying patients with severe pneumonia early in the clinical course, facilitating early ICU admission, because this has been shown to decrease the mortality rate.⁷ Different scoring systems such as the ATS/IDSA guidelines (developed by American Thoracic Society and Infectious Diseases Society of America), PIRO (Predisposition, Insult, Response and Organ dysfunction) scores for CAP, and Acute Physiology

and Chronic Health Evaluation score (APACHE II) and VAP PIRO score for VAP are used for assessing the severity of illness in pneumonia patients. It is still uncertain whether the use of any scoring system can lead to decreased mortality rates and more favorable outcomes in the management of patients with pneumonia. There is also interest in using biomarkers, such as procalcitonin (PCT), to diagnose the severity and guide the use and duration of antimicrobial therapy in patients with severe CAP and VAP.⁸⁻¹⁰

The emergence of multidrug-resistant (MDR) microorganisms is an alarming problem in the ICU and considerable forethought is necessary in choosing the right antibiotic to be used in this setting. In the ICU, almost 90% of episodes of nosocomial pneumonia occur in patients who are being mechanically ventilated for other reasons. Recent directives by the Centers for Medicare and Medicaid Services (CMS) and the Institute for Healthcare Improvement have led to the belief that VAP is preventable and should be a “never event” during the hospital stay. This may have led to underreporting in many instances.¹¹ Many ICUs have incorporated ventilator bundles as a preventive strategy to minimize VAP, which may be an effective strategy, even if not being able to completely eliminate the problem.

The incidence of pneumonia in nursing homes varies from 0.3 to 2.3 episodes per 1000 resident care days with a 30-day mortality rate of 14.7%.¹² In the 2005 ATS guidelines on nosocomial pneumonia, patients with exposure to MDR organisms by virtue of being in contact with the health care environment prior to admission were defined as having health care-associated pneumonia (HCAP). This group included residents of a nursing home or long-term care facility; recipients of recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days; and chronic hemodialysis patients.² The focus in managing these patients was to empirically treat for MDR pathogens. However, recent studies have shown that the HCAP population has significant heterogeneity, and that treatment of all patients does not always need to include coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) and drug-resistant gram-negative organisms.¹³

Pneumonia is unusual among medical illnesses because its pathogenesis, therapy, and prevention can be discussed, but there is tremendous controversy about how to best diagnose its presence. In this chapter we discuss the risk factors, pathogenesis, and recent advances in the treatment, complications, and various controversies that exist in the care of all forms of pneumonia patients in the ICU.

DEFINITIONS AND RISK FACTORS

Patients who are unable to mount an effective immune response are at increased risk of developing serious pneumonia. If the host defense mechanism is overwhelmed by the size of the inoculum, the virulence of the infecting microorganisms, or an excessive inflammatory response to infection, the patient can develop severe respiratory failure or sepsis. Depending on the time of onset and setting in which the infection developed, pneumonia is classified as community-acquired or nosocomial pneumonia, with specific definitions for VAP and HCAP among patients with nosocomial pneumonia (Box 42.1).

Box 42.1 Classification of Pneumonia

Community-Acquired Pneumonia (CAP)

An alveolar infection that develops in the outpatient setting or within 48 hours of admission to a hospital.

Nosocomial Pneumonia

Hospital-Acquired Pneumonia (HAP)

Pneumonia occurring ≥ 48 hours after hospital admission and not incubating at the time of admission.

Ventilator-Associated Pneumonia (VAP)

Pneumonia occurring ≥ 48 hours after endotracheal intubation and mechanical ventilation.

Health Care–Associated Pneumonia (HCAP)

Pneumonia in patients with one or more of the following risk factors for multidrug-resistant (MDR) bacteria: (1) hospitalization for ≥ 2 days in an acute care facility within 90 days before infection; (2) residence in a nursing home or long-term care facility; (3) antibiotic therapy, chemotherapy, or wound care within 30 days before current infection; (4) hemodialysis treatment at a hospital or clinic; (5) home infusion therapy or home wound care; or (6) family member with infection due to MDR pathogen.

SEVERE COMMUNITY-ACQUIRED PNEUMONIA

Even though there is no uniform definition for severe pneumonia, patients who require ventilator support or vasopressor support are generally regarded as having severe pneumonia, but it is more challenging to define severe illness in patients who are not receiving these interventions. However, identifying patients with severe pneumonia is important for proper resource utilization, and outcomes can be improved if these patients are identified early, avoiding delayed admission to the ICU, which is in itself a poor prognostic factor.

Several prognostic scoring systems were developed to predict the mortality risk and guide the site of care decision. The pneumonia severity index (PSI) and the British Thoracic Society's CURB-65 score help with determining mortality risk for patients with CAP.¹⁴ The PSI was developed to identify patients with a low risk of dying, placing all patients into five classes, based on the demographic characteristics, coexisting illnesses, physical examination findings, laboratory measurements, and radiographic findings. The ICU is most often used for patients in classes IV and V, who have a 30-day mortality risk of 4% to 10% and 27%, respectively.¹⁵ However, the PSI score may overestimate severity of illness in patients with older age, while underestimating severity in young patients without comorbid conditions.¹⁶ The complexity of the PSI contrasts with the simpler bedside scoring system, CURB-65. With this tool, 1 point is assigned each for the presence of confusion, blood urea nitrogen (BUN) greater than 7.0 mol/L (19.6 mg/dL), respiratory rate of 30 or more breaths/minute, systolic blood pressure 90 mm Hg or less, or diastolic blood pressure 60 mm Hg or less, and age 65 years or more.¹⁷ Mortality rate increases proportionately with scores higher than 3 (score 3, 17%; score 4, 41.5%; and score 5, 57%).

Severe pneumonia and the host inflammatory response to infection are determined by several variables, including the identity of the pathogen, the timeliness and appropriateness of therapy, and patient variables. The latter include the genetic makeup of the individual, age, nutritional status, sex, and comorbid medical conditions. Although the PSI and CURB-65 score performed well to determine mortality risk, there is still a need to identify patients who will need ICU level of care at the earliest possible time point.^{18,19} According to the 2007 ATS/IDSA guidelines, severe CAP is present if a patient requires invasive mechanical ventilation or vasopressors or has any three of the nine minor criteria (Box 42.2).¹⁹ The PIRO score has also been used and is calculated within 24 hours of ICU admission with 1 point assigned for each of comorbid conditions (chronic obstructive pulmonary disease [COPD], immunosuppressed state), age older than 70 years, multilobar opacities on chest radiograph, shock, severe hypoxemia, acute renal failure, bacteremia, and acute respiratory distress syndrome (ARDS). Patients can be stratified into four classes: (1) low, 0 to 2 points; (2) mild, 3 points; (3) high, 4 points; (4) very high, 5 to 8 points. In patients admitted to the ICU, the PIRO score had a better performance than APACHE II and ATS/IDSA criteria to predict 28-day mortality rate.¹⁸

Severe pneumonia is a dynamic inflammatory process, and predicting which stable-appearing patients will require ICU care later is difficult. Hence, critically ill patients who do not have obvious need for ICU care, such as invasive respiratory/vasopressor support (IRVS), must satisfy certain minor criteria in order to be recognized. However, the predictive value of using just three minor criteria alone for making a decision to admit to the ICU is uncertain, and in one study, the use of four minor criteria improved the accuracy of predicting subsequent need for ICU care.^{20,21} A recent prospective study from Scotland excluded patients with the two major ATS/IDSA criteria present on admission, and demonstrated that each of the nine minor criteria was associated with an increased risk of need for

mechanical ventilation, need for vasopressor support, and 30-day mortality.²²

Another system developed in Australia—SMART-COP—can assess the need for intensive respiratory or vasopressor support.²³ The SMART-COP was developed primarily to identify the need for IRVS. Different point scores were assigned to various parameters: low Systolic blood pressure less than 90 mm Hg (2 points), Multilobar pneumonia (1 point), low Albumin level less than 3.5 g/dL (1 point), high Respiratory rate 25 to 30 breaths/minute (1 point), Tachycardia higher than 125 beats/minute (1 point), Confusion (1 point), poor Oxygenation (2 points), and low arterial pH less than 7.35 (2 points). A score of more than 3 points identified 92% of patients requiring IRVS, with a specificity of 62.3%, outperforming PSI and CURB-65 scores to identify this specific end point.²³ The SMART-COP as well as the ATS/IDSA 2007 guidelines are the most accurate for predicting need for ICU care.²⁴

Renaud and coworkers examined risk factors for early admission to the ICU among 6560 patients, who presented to the emergency department and did not require immediate respiratory or circulatory support.²⁵ They identified 11 criteria independently associated with ICU admission: male gender, age younger than 80 years, comorbid conditions, respiratory rate of 30 breaths/minute or higher, heart rate of 125 beats/minute or higher, multilobar infiltrate or pleural effusion, white blood cell count less than 3 or more than 20 g/L, hypoxemia (oxygen saturation <90% or arterial partial pressure of oxygen [Pao₂] <60 mm Hg), BUN of 11 mmol/L or higher, pH less than 7.35, and sodium less than 130 mEq/L. They used these criteria to develop the risk of early admission to ICU index (REA-ICU index), which stratified patients into four risk classes, with the risk of ICU admission on days 1 to 3 ranging from 0.7% to 31%.²⁵

Recent data from the German Competence Network for the Study of CAP (CAPNETZ) Study Group demonstrated that serum biomarkers (PCT) can be used as good predictors for short- and long-term all-cause mortality rates in patients admitted with CAP.²⁶ A low level of PCT value in patients classified as high risk by PSI and CURB-65 scores predicted a low risk of dying, and probably a low need for ICU admission.²⁷ Ramirez and colleagues showed that the ATS/IDSA 2007 minor criteria had comparable predictive value with other scores, such as CURB-65 and SMART-COP, but that the use of biomarkers like PCT and C-reactive protein (CRP), along with minor criteria, helped in predicting the need for delayed ICU admission.²⁸ Pathophysiologic severity markers of severe sepsis, like soluble receptor for advanced glycation end products (SRAGE) along with severity scores have been examined in patients with CAP and are encouraging but need further studies for validation.²⁹

Box 42.2 Severe Pneumonia: Diagnostic Criteria*

Major Criteria

Invasive mechanical ventilation
Use of vasopressors to maintain blood pressure

Minor Criteria

Respiratory rate ≥ 30 breaths/min
Multilobar infiltrates
New onset confusion/disorientation
Uremia (BUN > 20 mg/dL)
Leukopenia (WBC count < 4000 cells/ μ L)
Pao₂/Fio₂ ratio ≥ 250
Thrombocytopenia (platelet count $< 100,000$ cells/ μ L)
Hypothermia (core temperature $< 36^\circ$ C)
Hypotension requiring aggressive fluid resuscitation

*According to ATS/IDSA 2007 Guidelines.

ATS/IDSA, American Thoracic Society/Infectious Diseases Society of America; BUN, blood urea nitrogen; WBC, white blood cell.

RISK FACTORS FOR SEVERE FORMS OF COMMUNITY-ACQUIRED PNEUMONIA

Most patients with severe CAP (45-65%) have coexisting illnesses, and patients who are chronically ill have an increased likelihood of developing a complicated pneumonia illness (Box 42.3).³⁰ The most common chronic illnesses in these patients are respiratory disease such as COPD, cardiovascular disease, and diabetes mellitus. In addition, certain habits such as cigarette smoking and

Box 42.3 Risk Factors for Development of Severe Community-Acquired Pneumonia (CAP)

Advanced age (>65 years)
 Comorbid illness: chronic respiratory illness (including COPD), cardiovascular disease, diabetes mellitus, neurologic illness, renal insufficiency, malignancy
 Cigarette smoking (risk for pneumococcal bacteremia)
 Alcohol abuse
 Absence of antibiotic therapy before hospitalization
 Failure to contain infection to its initial site of entry
 Immune suppression
 Genetic polymorphisms in the immune response

COPD, chronic obstructive pulmonary disease.

alcohol abuse are also quite common in those with severe CAP, and cigarette smoking has been identified as a risk factor for bacteremic pneumococcal infection.³¹ Other common illnesses in those with CAP include malignancy and neurologic illness (including seizures). Milder forms of pneumonia may be more severe on presentation, if patients have not received antibiotic therapy prior to hospital admission. In addition, genetic differences in the immune response may predispose certain individuals to more severe forms of infection and adverse outcomes and may be reflected by a family history of severe pneumonia or adverse outcomes from infection.³² Also, genetic variability of the pulmonary surfactant proteins A and D may affect clearance of microorganisms and the extent of the inflammatory response, influencing the severity and outcomes for patients with CAP, notably missense single nucleotide polymorphisms and haplotypes of SFTP1, SFTP2, and SFTP3.³³ Recent evidence also provides insights on the risk of developing pneumonia in patients taking inhaled corticosteroids. In a meta analysis of 18 randomized controlled trials with a total of 16,996 patients, inhaled corticosteroids were associated with a significantly increased risk of serious pneumonia when compared with placebo (relative risk [RR] 1.81; $P < 0.001$) or when the combination of inhaled corticosteroids and long-acting β -agonists was compared with long-acting β -agonists (RR 1.68; $P < 0.002$).³⁴ However, the mortality rate of patients developing CAP while on inhaled corticosteroids may actually be lower than in patients not receiving this therapy.

MORTALITY RISK FROM COMMUNITY-ACQUIRED PNEUMONIA

In a meta analysis of 33,148 patients with CAP, the overall mortality rate was 13.7%, but those admitted to the ICU had a mortality rate of 36.5%.⁵ Eleven prognostic factors were significantly associated with different odds ratios (OR) for mortality rate: male sex (OR = 1.3), pleuritic chest pain (OR = 0.5), hypothermia (OR = 5.0), systolic hypotension (OR = 4.8), tachypnea (OR = 2.9), diabetes mellitus (OR = 1.3), neoplastic disease (OR = 2.8), neurologic disease (OR = 4.6), bacteremia (OR = 2.8), leukopenia (OR = 2.5), and multilobar infiltrates (OR = 3.1). In other studies, the clinical features that predict a poor outcome (Box 42.4) include

Box 42.4 Risk Factors for Poor Outcome from Community-Acquired Pneumonia (CAP)

Patient-Related Factors

Male gender
 Absence of pleuritic chest pain
 Nonclassical clinical presentation (nonrespiratory presentation)
 Neoplastic illness
 Neurologic illness
 Age >65 years
 Family history of severe pneumonia or death from sepsis

Abnormal Physical Findings

Respiratory rate >30 breaths/min on admission
 Systolic (<90 mm Hg) or diastolic (<60 mm Hg) hypotension
 Tachycardia (>125 beats/min)
 High fever (>40°C) or afebrile
 Confusion

Laboratory Abnormalities

BUN >20 mg/dL
 Leukocytosis or leukopenia
 Multilobar radiographic abnormalities
 Rapidly progressive radiographic abnormalities during therapy
 Bacteremia
 Hyponatremia (serum sodium <130 mmol/L)
 Multiple organ failure
 Respiratory failure
 Hypoalbuminemia
 Arterial pH <7.35
 Pleural effusion

Pathogen-Related Factors

High-risk organisms: type III pneumococcus, *Staphylococcus aureus*, gram-negative bacilli (including *Pseudomonas aeruginosa*), aspiration organisms, SARS coronavirus
 Possibly high levels of penicillin resistance (MIC of at least 4 mg/L) in pneumococcus

Therapy-Related Factors

Delay in initial antibiotic therapy (more than 4–6 hours)
 Initial therapy with inappropriate antibiotic therapy
 Lack of clinical response to empiric therapy within 72 hours

BUN, blood urea nitrogen; MIC, minimum inhibitory concentration; SARS, severe acute respiratory syndrome.

advanced age (>65 years), preexisting chronic illness of any type, the absence of fever on admission, respiratory rate more than 30 breaths/minute, diastolic or systolic hypotension, elevated BUN (>19.6 mg/dL), profound leukopenia or leukocytosis, inadequate antibiotic therapy, need for mechanical ventilation, hypoalbuminemia, and the presence of certain “high-risk” organisms (type III pneumococcus, *S. aureus*, gram-negative bacilli, aspiration organisms, or postobstructive pneumonia). Timing of initial appropriate antibiotics is also important, with a delay in the initiation of appropriate antibiotic therapy of more than 4 hours being associated with increased mortality risk.^{35–37} Other clinical features associated with an increased mortality risk include rapid radiographic progression during therapy,

nonrespiratory clinical presenting symptoms, and the presence of HCAP risk factors.

Many studies suggest that early ICU admission confers a better outcome in patients with severe CAP than delayed admission. In a study comparing patients directly admitted to the ICU from the emergency department to those moved to the ICU within 3 days after admission, delayed-transfer patients had a higher 28-day mortality rate (23.4% vs. 11.7%; $p = 0.02$) and a longer median hospital length of stay (13 days vs. 7 days; $p < 0.001$).³⁸ In a study of 17,869 cases of CAP in the United Kingdom, only 5.9% needed ICU care, but early admission (within 2 days of hospitalization) appeared to be preferable and was associated with a lower mortality rate (46.3%) than was late admission (>7 days in the hospital, 57.6% mortality rate).⁷ In patients with severe CAP, the expected mortality rate for those admitted to the ICU is 35% to 40%, but higher rates have been observed if the percentage of patients who are mechanically ventilated is higher than 60%, implying that the prognosis is worse if ICU care is first provided late in the course of illness, after the onset of overt respiratory failure.⁷ Restrepo and colleagues noted that late admission to the ICU, more than 24 hours after presentation in patients with severe CAP, resulted in a higher mortality rate than did early admission (47.4% vs. 23.2%, $p = 0.02$; hazard ratio 2.6).³⁹

PNEUMONIA ACQUIRED IN THE HOSPITAL

Hospital-acquired pneumonia (HAP) is the second most common nosocomial infection in the United States,⁴⁰ and current guidelines have emphasized the importance of the time of onset of the disease and the presence of risk factors for infection due to MDR pathogens in defining the approach to therapy. The major goals are early, appropriate antibiotic therapy in adequate doses and appropriate de-escalation of initial antibiotic therapy, based on microbiologic cultures and the clinical response of the patient.²

Early- and late-onset HAP and VAP are diagnosed 2 to 5 days, and more than 5 days, after hospitalization, respectively. The pathogens associated with early-onset HAP and VAP are a group of “core pathogens,” including *Streptococcus pneumoniae*, *Haemophilus influenzae*, methicillin-susceptible *Staphylococcus aureus* (MSSA), and enteric gram-negative bacilli (*Escherichia coli*, *Klebsiella* species, *Proteus* species, and *Enterobacter* species). In contrast, late-onset HAP and VAP are caused by all the core pathogens, plus drug-resistant pathogens such as MRSA and MDR gram-negative bacilli (*Pseudomonas aeruginosa*, *Acinetobacter* species, *Enterobacter* species, and extended-spectrum β -lactamase [ESBL]-positive strains).

Unlike CAP, there are no well-studied scoring systems to assess disease severity in patients with HAP and VAP. Clinical studies have used surrogate markers such as the APACHE II, or the Sequential Organ Failure Assessment (SOFA) score as a measure of organ dysfunction and severity assessment.⁴¹ The Clinical Pulmonary Infection Score (CPIS) was originally introduced for diagnoses in patients with VAP (described later in the text), but it has also been used to follow the response of VAP patients to therapy.⁴² The value of APACHE II, SOFA score, and CPIS in the prediction of mortality risk during VAP episodes was assessed in a prospective observational study, which found that an APACHE II

score greater than 16 (determined at the time of VAP diagnosis) was the only independent predictor of the mortality risk (OR 5; $p = 0.019$) in a logistic regression analysis.⁴³ In a prospective study by Lisboa and colleagues from Spain, including 441 patients with VAP in three multidisciplinary ICUs, the mortality risk in patients with VAP was assessed by a simple four-variable VAP PIRO score: comorbid conditions (COPD, immunocompromised state, heart failure, cirrhosis, or chronic renal failure); bacteremia; systolic blood pressure less than 90 mm Hg; and ARDS.⁴⁴ Patients were stratified into three levels of risk: (1) mild, 0 to 1 points; (2) high, 2 points (hazard ratio, 2.14); and (3) very high, 3 to 4 points (hazard ratio, 4.63). More recently, a newer and easier scoring system, the IBMP-10, was proposed and is based on the presence of immunodeficiency; (2) blood pressure less than 90 mm Hg (systolic) or less than 60 mm Hg (diastolic); multilobar infiltrates noted on a chest radiograph; platelet count less than 100,000/ μ L; and duration of hospitalization before the onset of VAP of more than 10 days.⁴⁵ IBMP-10 score was comparable to the APACHE II score in its ability to predict mortality risk in patients with VAP but needs further validation in prospective studies.

RISK FACTORS ASSOCIATED WITH NOSOCOMIAL PNEUMONIA

The 2005 ATS/IDSA guidelines characterized the predisposing factors for developing nosocomial pneumonia as modifiable and nonmodifiable. Mechanical ventilation (for > 2 days) is the most important risk factor for nosocomial pneumonia, but other identified risks include age older than 60, malnutrition (serum albumin < 2.2 g/dL), acute lung injury (ARDS), coma, burns, recent abdominal or thoracic surgery, multiple organ failure, transfusion of more than 4 units of blood, transport from the ICU, prior antibiotic therapy, elevation of gastric pH (by antacids or histamine-type 2 blocking agents), large volume aspiration, use of a nasogastric tube (rather than a tube placed in the jejunum or a tube inserted through the mouth), use of inadequate endotracheal tube cuff pressure, prolonged sedation and paralysis, maintaining patients in the supine position in bed, use of total parenteral nutrition (TPN) feeding rather than enteral feeding, and repeated reintubation.² When a patient is mechanically ventilated, the risk of pneumonia is greatest in the first 5 days (3% per day), and declines thereafter to a risk of 2% per day for days 6 to 10, and to a rate of 1% per day or lower after this.⁴⁶ Noninvasive ventilation for respiratory failure is associated with a much lower risk of pneumonia than endotracheal intubation.

The relation between pneumonia and ARDS is particularly interesting, because up to one third of all cases of ARDS may be the result of pneumonia, and in some series, pneumonia is the most common cause of acute lung injury. In addition, secondary nosocomial pneumonia is the most common infection complicating the course of established ARDS.^{47,48} Seidenfeld and coworkers reported better survival in patients with ARDS in the absence of infection, but a subanalysis for pneumonia was not available.⁴⁸ In a study by Chastre and colleagues of 243 consecutive patients who required mechanical ventilation 48 or more hours, 55% of the ARDS patients developed VAP compared to 28% without ARDS ($p = 0.0005$).⁴⁹ Most patients who developed VAP had

been treated with prior broad-spectrum antibiotics, and were infected with MDR pathogens (MRSA, nonfermenting gram-negative bacilli, and Enterobacteriaceae).

Pneumonia also presents a particular problem in the postoperative patient, particularly after elective thoracic, cardiac, or abdominal surgery. Other surgical groups that are at high risk for pneumonia include the victims of major trauma, particularly those suffering head injury and blunt chest trauma. When a patient has a pulmonary contusion, it may be very difficult to distinguish this process from secondary lung infection on the basis of clinical and radiographic findings.

MORTALITY RISK FROM VENTILATOR-ASSOCIATED PNEUMONIA

Mortality rates from VAP can be as high as 50% to 70%, and case-control studies have documented death directly attributable to the presence of pneumonia.⁵⁰ The patients with HAP often have other associated comorbid illnesses that predispose them to a high risk of dying, independent of the presence of pneumonia. Attributable mortality rate, defined as death directly related to infection and not due to underlying conditions, is challenging to measure, but older studies reported a higher mortality rate for patients with VAP than for similarly ill ventilated patients without VAP (52.4% with VAP, compared to 22.4% for patients without).⁵¹ Recently, however, Bekaert and colleagues assessed the population-attributable risk of ICU VAP by taking into account the confounding that is caused by time-dependent severity-of-illness indicators.⁵² They estimated that 4.4% (95% confidence interval, 1.6-7.0%) of the deaths in the ICU on day 30 and 5.9% (95% confidence interval, 2.5-9.1%) on day 60 were attributable to VAP. This corresponds to an ICU attributable mortality rate for VAP of about 1% on day 30 and 1.5% on day 60.

Antibiotic-resistant organisms may add to the mortality risk of VAP, not because of increased virulence, but rather because these organisms are often not anticipated, and when present, are often initially treated with ineffective antibiotic regimens.⁵³ The factor associated with the greatest impact on attributable mortality rate is the accuracy and timeliness of initial antibiotic therapy. Use of the wrong therapy, or delays in the initiation of therapy, are the most important predictors of VAP mortality rate.⁵⁴ Initial appropriate therapy (using an agent to which the etiologic pathogen is sensitive) can reduce mortality rate, but administration of correct therapy at a later date, after initially incorrect therapy, may not effectively reduce mortality rate.⁵⁴ The benefit of accurate empiric therapy may not apply to all patients, but may be greatest for those infected with *P. aeruginosa* or *S. aureus*⁵⁵ and for those without the most severe degree of multiple organ dysfunction at the time of therapy.⁵⁶ For some patients, even using the correct therapy does not reduce the risk of death if it is not given in adequate doses and if the therapy does not reach the site of infection.

Although a number of host and bacteriologic factors enhance the mortality risk of nosocomial pneumonia, development of a superinfection, as opposed to primary nosocomial pneumonia, is a particularly ominous finding. Rello and associates observed that pulmonary superinfection had a 67% mortality rate, whereas primary nosocomial pneumonia had a 38% mortality rate.⁵⁷ In earlier studies, Graybill

and coworkers observed a 62% mortality rate with superinfection pneumonia, compared to a 40% mortality rate for primary nosocomial lung infection.⁵⁸ These data, as well as information from Fagon and colleagues, emphasize the important role of prior antibiotics in enhancing mortality risk, an outcome that is likely the result of secondary infection by more virulent pathogens.^{59,60} As a result, antibiotic use has two pivotal roles in prognosticating outcome from nosocomial pneumonia: outcome is improved if the correct therapy is chosen, but if this therapy is followed by superinfection, then mortality risk is increased, generally because these infections involve difficult-to-treat drug-resistant organisms. Closely related to antibiotic resistance is the presence of bacteremia in patients with VAP, which is associated with increased mortality risk.⁶¹

When therapy is given, it is important to decrease the number and spectrum of antimicrobial therapy once culture data become available, referred to as “de-escalation.” Several recent studies have demonstrated that the use of de-escalation is associated with lower mortality risk compared to escalation or compared to a strategy of making no effort to reduce antibiotic therapy.⁶²⁻⁶⁴ The choice of how to administer a specific agent can also affect outcome, and one study of MRSA VAP found that the mortality risk with intermittent infusion of vancomycin was twice as high as when this agent was administered by continuous infusion.⁶⁵ Other risk factors for mortality (Box 42.5) include prolonged duration of ventilation, coma on admission, creatinine greater than 1.5, transfer from another ward to the ICU, the presence of certain high-risk pathogens (particularly an antibiotic-resistant organism such as *P. aeruginosa*, *Acinetobacter* spp., or *S. aureus*), bilateral radiographic abnormalities, age older than 60 years, ultimately fatal underlying

Box 42.5 Mortality Risk Factors for Nosocomial Pneumonia

Historical Data

- Prior antibiotic therapy
- Age >60 years
- Underlying fatal illness
- Prolonged mechanical ventilation
- Inappropriate antimicrobial therapy
- Transfer to the intensive care unit from another ward

Physiologic Findings

- Respiratory failure
- Coma on admission
- Multiple system organ failure
- APACHE II score rising to greater than 20 at 72 hours after diagnosis

Laboratory Findings

- Serum creatinine >1.5 mg/dL
- Gram-negative pneumonia, especially *Pseudomonas* or *Acinetobacter* infection
- Infection with any drug-resistant pathogen
- Bilateral radiographic abnormalities
- Fungal pneumonia
- Polymicrobial infection

APACHE II, Acute Physiology and Chronic Health Evaluation II [study].

condition, shock, prior antibiotic therapy, multiple system organ failure, nonsurgical primary diagnosis, and a rising APACHE II score during pneumonia therapy.^{2,66}

HEALTH CARE–ASSOCIATED PNEUMONIA

The ATS/IDSA guidelines included HCAP as a form of nosocomial pneumonia because these patients were at risk for infection with MDR pathogens because of recent contact with the health care environment. HCAP includes patients who were hospitalized in an acute care hospital for 2 or more days within 90 days of the infection; those who reside in a nursing home or long-term care facility; individuals who received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days; and those attending a hospital or hemodialysis clinic. Recent clinical investigations have shown that HCAP includes a diverse group of patients, with some at risk for MDR organisms and others not. In fact, many HCAP patients have been treated successfully with a monotherapy regimen or with regimens used for CAP.¹³ Patients in the HCAP population who are at risk for MDR pathogens were those with severe illness or those with other risk factors including hospitalization in the past 90 days, antibiotic therapy in the past 6 months, poor functional status as defined by activities of daily living score, and immune suppression.

PATHOGENESIS

GENERAL OVERVIEW

The respiratory system has both innate and adaptive immunity, which helps prevent potentially harmful pathogens

from adhering to the respiratory mucosa and proliferating. Multiple defense barriers in the conducting and gas exchange surfaces of the respiratory tract filter out invading pathogens. The combined effects of the physical, innate, and acquired host defense systems serve to recognize, localize, kill, and remove pathogens. The pathogens that reach the conducting airways are exposed to the soluble constituents in airway fluids. Multiple antimicrobial peptides, such as lysozyme (lytic to bacterial membranes); lactoferrin (which excludes iron from bacterial metabolism); IgA and IgG; and defensins are present in the airway mucosa and pathogens are expelled by the coordinated mucociliary system and cough reflex. Particles 1 μm and smaller reach the alveolar surface and interact with the alveolar macrophages and other components such as IgG, complement, surfactant, and surfactant-associated proteins. Bacteria are opsonized by IgG, complement, or surfactant proteins SP-A and SP-D and are ingested by alveolar macrophages. Pathogen recognition is mediated by toll-like receptors. They initiate local inflammatory response by releasing interleukins and cytokines and carry microbial antigens into the interstitium and to regional lymph nodes where they are taken up by specialized dendritic cells and presented to responding lymphocytes to initiate adaptive immune responses.⁶⁷

Pneumonia develops when these host defenses are overwhelmed by the invading microorganisms (Fig. 42.1). This may occur because the patient has an inadequate immune response, often as the result of underlying comorbid illness, which can lead to anatomic abnormalities (endobronchial obstruction, bronchiectasis), disease-associated immune impairment, or therapy-induced dysfunction of the immune system (corticosteroids, endotracheal intubation).^{2,68,69} Pneumonia can also occur in patients who have an adequate immune system if the host defense system is

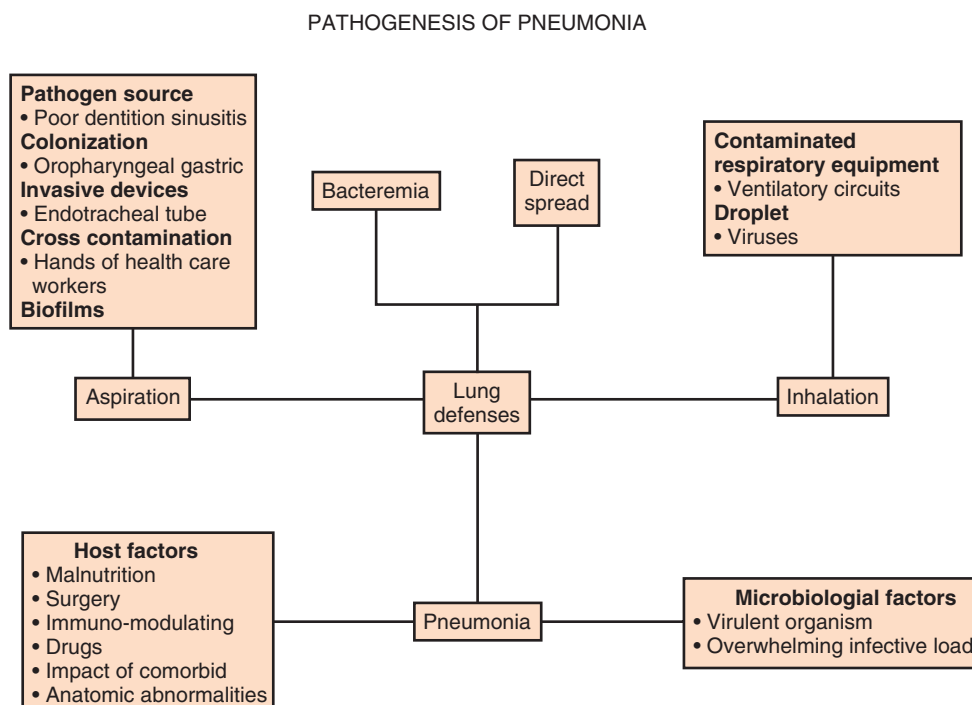

Figure 42.1 Different routes of entry for pathogenic organisms into the respiratory tract are shown. The innate and adaptive immune systems try to contain the infection while host and microbiologic factors modulate the lung's response to the pathogen.

overwhelmed by a large inoculum of bacteria (massive aspiration) or by a particularly virulent organism to which the patient has no preexisting immunity (such as an endemic virus) or to which the patient has an inability to form an adequate immune response. With this paradigm in mind, it is easy to understand why previously healthy individuals develop infection with virulent pathogens such as viruses (influenza), *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *S. pneumoniae*. However, for chronically ill patients, it is possible for them to be infected not only by these virulent organisms but also by organisms that are not highly virulent. Owing to host defense impairments, organisms that commonly colonize these patients can cause infection as a result of an inadequate immune response. These organisms include enteric gram-negative bacteria (*E. coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, *Acinetobacter* spp.) and fungi (*Aspergillus* and *Candida* spp.). There can also be genetic variations in the immune response, making some patients prone to overwhelming infection, due to an inadequate response, and others prone to acute lung injury, due to an excessive immune response.³² In fact, the failure to localize the immune response to the respiratory site of initial infection may explain why some patients develop acute lung injury and sepsis as the inflammatory response extends to the entire lung and systemic circulation.⁷⁰

ROUTE OF ENTRY

Bacteria can enter the lung via several routes, but aspiration from a previously colonized oropharynx is the most common way that patients develop pneumonia. Although most pneumonias result from microaspiration, patients can also aspirate large volumes of bacteria if they have impaired neurologic protection of the upper airway (stroke, seizure), or if they have gastrointestinal illnesses that predispose to vomiting. Other routes of entry include inhalation, which applies primarily to viruses, *L. pneumophila*, and *Mycobacterium tuberculosis*; hematogenous dissemination from extrapulmonary sites of infection (right-sided endocarditis); and direct extension from contiguous sites of infection. In critically ill hospitalized patients, bacteria can also enter the lung from a colonized stomach (spreading retrogradely to the oropharynx, followed by aspiration), from a colonized or infected maxillary sinus, from colonization of dental plaque, or directly via the endotracheal tube (from the hands of staff members). Studies have also shown that the use of nasal tubes (into the stomach or trachea), can predispose to sinusitis and pneumonia, but that a gastric source of pneumonia pathogens in ventilated patients is not common.^{71,72}

COLONIZATION OF THE UPPER RESPIRATORY SYSTEM AND DIGESTIVE TRACT

Colonization of the upper respiratory and digestive tracts with pathogenic microorganisms is a major risk factor for the development of pneumonia.⁷³ Factors enhancing airway colonization include antibiotic therapy, endotracheal intubation, smoking, malnutrition, general surgery, dental plaque, and therapies that elevate the gastric pH.⁷⁴ The stomach can be the source of 30% of the enteric

gram-negative bacteria that colonize the trachea of intubated patients, but it is difficult to decide if such colonization leads to pneumonia. In a recent multicenter randomized controlled study by Lacherade and colleagues, the use of intermittent subglottic secretion drainage resulted in a significant reduction in microbiologically confirmed VAP compared to control subjects (14.8% vs. 25.6%; $P = 0.02$),⁷⁵ without a significant difference in the duration of mechanical ventilation and hospital mortality rate. The findings suggest that interruption of gastric to oral to tracheal transmission of bacteria can help to prevent VAP. The importance of oral colonization in VAP pathogenesis was shown in a study by DeRiso and coworkers, which demonstrated that the use of the oral antiseptic chlorhexidine in 353 patients undergoing coronary artery bypass surgery significantly reduced the incidence of respiratory tract infections by 69%.⁷⁶ It has become difficult to separate colonization from infection in intubated patients, particularly with the recognition of ventilator-associated tracheobronchitis (VAT).⁷⁷ VAT patients have an infection, with clinical signs (fever, leukocytosis, and purulent sputum) and microbiologic findings (Gram stain with bacteria and leukocytes, with either a positive semiquantitative or a quantitative sputum culture) but the absence of a new infiltrate on chest radiograph. It remains uncertain if VAT can progress to VAP, or if the two events are independent of one another. If VAT is a precursor of VAP, then serial surveillance cultures of endotracheal aspirates could identify MDR pathogens for targeted antibiotic treatment when VAT is present, in an effort to prevent VAP.⁷⁸

THE ROLE OF RESPIRATORY THERAPY EQUIPMENT AND ENDOTRACHEAL TUBES

The endotracheal tube bypasses the filtration and host defense functions of the upper airway and can act as a conduit for direct inoculation of bacteria into the lung. This route may be particularly important if bacteria form a biofilm and colonize the inside of the endotracheal tube itself.^{79,80} This can occur if tracheobronchial organisms reach the endotracheal tube, a site where they are able to proliferate free from any impediment by the host defense system. Bacteria commonly do grow at this location in a biofilm, which promotes the growth of MDR organisms.⁸⁰ The biofilm represents a “sequestered nidus” of infection on the inside of the endotracheal tube, and particles can be dislodged every time the patient is suctioned. This is one of the mechanisms explaining the strong association between endotracheal intubation and pneumonia. Given the presence of biofilm in endotracheal tubes, it may be tempting to regularly reintubate patients and use a fresh tube, but this approach is not recommended because reintubation is itself a risk factor for VAP.⁸¹ Afessa and colleagues reported that the use of the silver-coated tube reduced the mortality rate of patients who developed VAP despite having the silver tube in place, compared with the mortality rate of patients who developed VAP with a standard tube in place (14% vs. 36%; $P = 0.03$).⁸² However, the overall mortality rate was high in patients with the silver tube, and the rate of death from respiratory failure was higher in the silver tube–treated patients than those with the standard tube (19% vs. 11%, $P = 0.02$), raising doubts on the impact of using the

silver-coated tube on VAP patients. Other interventions, such as use of devices to remove biofilm from the tube interior and the coating of tubes with mimics of antimicrobial peptides (ceragenins), are in development to interrupt the pathogenesis of VAP.⁸³

Just as a patient's own tracheobronchial flora can spread to the endotracheal tube and amplify to large numbers, a similar phenomenon can occur in respiratory therapy equipment and in ventilator circuits.^{84,85} Ventilator circuit colonization has been studied and the greatest bacterial numbers are found at sites nearest to the patient, not the ventilator, suggesting that circuit contamination originates from the patient.⁸⁴ One highly contaminated site is the condensate in the tubing, and this material can inadvertently be inoculated into patients if the tubing is not handled carefully. Because condensate colonization occurs in 80% of tubings within 24 hours, it does not appear that frequent ventilator circuit changes are useful or even able to reduce the risk of pneumonia; in one study, tubing changes every 24 hours (rather than every 48 hours) served as a risk factor for pneumonia.⁸⁶ Although most patients have ventilator tubing changed every 48 hours, several studies have shown no increased risk of infection if tubing is never changed or changed infrequently.^{87,88} The use of heat moisture exchangers may be one way to avoid this problem, but they have had an inconsistent effect on preventing VAP. In addition, frequent changes of heat moisture exchangers (i.e., every 24 hours) have not been shown to have an impact on the incidence of VAP, and heat moisture exchangers should be changed no more frequently than every 48 hours.⁸⁹

CLINICAL FEATURES

HISTORICAL INFORMATION

Pneumonia is generally characterized by symptoms of fever, cough, purulent sputum production, and dyspnea in a patient with a new or progressive lung infiltrate, with or without an associated pleural effusion. In nonventilated patients, cough is the most common finding and is present in up to 80% of all CAP patients, but is less common in those who are elderly, those with serious comorbid conditions, and individuals coming from nursing homes. Patients with CAP and an intact immune system generally have classic pneumonia symptoms, but the elderly patient can have a nonrespiratory presentation with symptoms of confusion, falling, failure to thrive, altered functional capacity, or deterioration in a preexisting medical illness, such as congestive heart failure.⁹⁰ The absence of clear-cut respiratory symptoms and an afebrile status have themselves been identified as predictors of an increased risk of death. Pleuritic chest pain is also commonly seen in patients with CAP, and in one study, its absence was also identified as a poor prognostic finding.⁹¹ A recent study pointed out that nonsteroidal anti-inflammatory drugs prior to hospitalization were associated with a higher chance of developing pleuropulmonary complications (OR = 8.1).⁹²

Certain clinical conditions are associated with specific pathogens in patients with CAP, and these associations should be evaluated when obtaining a history (Box 42.6).¹⁹ For example, if the presentation is subacute, following

Box 42.6 Epidemiologic Conditions and Related Specific Pathogens in Community-Acquired Pneumonia (CAP)

Chronic obstructive pulmonary disease: *Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Legionella* species, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Chlamydia pneumoniae*

Structural lung disease: *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Staphylococcus aureus*

Alcoholism: *S. pneumoniae*, oral anaerobes, *Klebsiella pneumoniae*, *Acinetobacter* species, *Mycoplasma tuberculosis*

Lung abscess: CA-MRSA, oral anaerobes, endemic fungal pneumonia, *M. tuberculosis*, atypical mycobacteria

Exposure to birds: *Chlamydophila psittaci*, *Histoplasma capsulatum*

Exposure to rabbits: *Francisella tularensis*

Exposure to farm animals or parturient cats: *Coxiella burnetii* (Q fever)

Hotel or cruise ship stay in previous 2 weeks: *Legionella* species

Travel to or residence in southwestern United States: *Coccidioides* species, hantavirus

Travel to or residence in Southeast and East Asia: *Burkholderia pseudomallei*, avian influenza virus, SARS coronavirus

Injection drug use: *S. aureus*, anaerobes, *M. tuberculosis*, *S. pneumoniae*

Bioterrorism: *Bacillus anthracis*, *Yersinia pestis*, *F. tularensis*

CA-MRSA, community-associated methicillin-resistant *S. aureus*; SARS, severe acute respiratory syndrome.

contact with birds, rats, or rabbits, then the possibility of psittacosis, leptospirosis, tularemia, or plague, respectively, should be considered. *Coxiella burnetii* (Q fever) is a concern with exposure to parturient cats, cattle, sheep, or goats; hantavirus with exposure to mice droppings in endemic areas; and *Legionella* with exposure to contaminated water sources (saunas). Following influenza, superinfection with pneumococcus, *S. aureus* (including MRSA), and *H. influenzae* should be considered. With travel to endemic areas in Asia, the onset of respiratory failure after a preceding viral illness should lead to suspicion of a viral pneumonia, which could be severe acute respiratory syndrome (SARS) or avian influenza.⁹³ Endemic fungi (coccidioidomycosis, histoplasmosis, and blastomycosis) occur in well-defined geographic areas and may present acutely with symptoms that overlap with acute bacterial pneumonia. Clinicians should also be cognizant of the risk of bioterrorism and be able to detect clinical features of *Bacillus anthracis*, *Yersinia pestis*, and *Francisella tularensis*.

Nosocomial pneumonia often presents with less definitive clinical findings, particularly in those who are mechanically ventilated, in which the clinical diagnosis is made in patients with a new or progressive radiographic infiltrate, along with some indication that infection is present (fever, purulent sputum, or leukocytosis). In addition, some patients can have purulent sputum and fever, without a new infiltrate, and be diagnosed as having purulent tracheobronchitis, an infectious complication of mechanical ventilation (VAT) that may also require antibiotic therapy, but is not

pneumonia.² In taking a history from a patient with nosocomial pneumonia, it is important to identify if there are risk factors present for drug-resistant organisms. For ventilated patients, these factors include prolonged ICU stay (≥ 5 days), recent antibiotic therapy, and the presence of HCAP risks.^{2,60} In CAP patients, risk factors for drug-resistant pneumococcus include recent β -lactam therapy, exposure to a child in day care, alcoholism, immune suppression, and multiple medical comorbid conditions.^{94,95}

PHYSICAL EXAMINATION

Physical findings of pneumonia include tachypnea, crackles, rhonchi, and signs of consolidation (egophony, bronchial breath sounds, dullness to percussion). Patients should also be evaluated for signs of pleural effusion. In addition, extrapulmonary findings should be sought to rule out metastatic infection (arthritis, endocarditis, meningitis) or to add to the suspicion of an “atypical” pathogen, such as *M. pneumoniae* or *C. pneumoniae*, which can lead to such complications as bullous myringitis, skin rash, pericarditis, hepatitis, hemolytic anemia, or meningoencephalitis. One of the most important ways to recognize severe CAP early in the course of illness is to carefully count the respiratory rate.^{96,97} In the elderly, an elevation of respiratory rate can be the initial presenting sign of pneumonia, preceding other clinical findings by as much as 1 to 2 days and tachypnea is present in over 60% of all patients, being present more often in the elderly than in younger patients with pneumonia.⁹⁷ In addition, the counting of respiratory rate can identify the patient with severe illness, who commonly has a rate more than 30 breaths/minute. Gurgling sounds heard during quiet breathing or speech have been independently associated with HAP.⁹⁸ Overall, the clinical diagnosis of pneumonia has moderate sensitivity (79%) and specificity (66%),⁹⁹ and in general, definitive imaging studies are required in critically ill patients.

ETIOLOGIC PATHOGENS

COMMUNITY-ACQUIRED PNEUMONIA

The microorganisms causing CAP may vary according to geographic area and underlying patient risk factors. Even with extensive diagnostic testing, an etiologic agent is defined in only about half of all patients with CAP, pointing out the limited value of diagnostic testing, and the possibility that we do not know all the organisms that can cause CAP. The most common cause of CAP is pneumococcus (*S. pneumoniae*), an organism that is frequently (at least 40% of the time) resistant to penicillin or other antibiotics, leading to the term drug-resistant *Streptococcus pneumoniae* (DRSP). Fortunately, most penicillin resistance in the United States is still more commonly of the “intermediate” type (penicillin minimum inhibitory concentration, or MIC, of 0.1 to 1.0 mg/L) and not of the high-level type (penicillin MIC of 2.0 mg/L or more).¹⁰⁰ Pneumococcal resistance to other antibiotics is also common, including macrolides and trimethoprim-sulfamethoxazole, but the clinical relevance and impact on outcome of these in vitro findings is uncertain, and most experts believe that only organisms with a

penicillin MIC of 4 mg/L or more are associated with an increased risk of death.¹⁰¹ Recently, the U.S. definitions of resistance have changed for nonmeningeal infection, with sensitive being defined by a penicillin MIC of 2 mg/L or less, intermediate as an MIC of 4 mg/L, and resistant as an MIC of 8 mg/L or more. With these new definitions of resistance, very few pathogens will be defined as resistant, but those that are may affect outcome.

All patients with severe CAP should be considered to be at risk for DRSP, and in addition, those admitted to the ICU can have infection with atypical pathogens, which account for up to 20% of infections, either as primary infection or as copathogens. The identity of these organisms varies over time and geography. In some areas, *Legionella* is a common cause of severe CAP, although in others *C. pneumoniae* or *M. pneumoniae* predominate.³⁰ Other important causes of severe CAP include *H. influenzae*, *S. aureus*, which includes MRSA (especially after influenza), and enteric gram-negative organisms (including *P. aeruginosa*) in patients with appropriate risk factors (particularly bronchiectasis and steroid-treated COPD).

Recently, a toxin-producing strain of MRSA has been described to cause CAP in patients after influenza and other viral infections (Fig. 42.2). This community-acquired MRSA (CA-MRSA) is biologically and genetically distinct from the MRSA that causes nosocomial pneumonia, being more virulent and necrotizing, and associated with the production of the Panton-Valentine leukocidin (PVL).^{102,103} Viruses can be a cause of severe CAP, including influenza virus, as well as parainfluenza virus and epidemic viruses such as coronavirus (which caused SARS) and avian influenza.⁹³ Viral pneumonia (SARS and influenza) can lead to respiratory failure, and occasionally tuberculosis or endemic fungi can result in severe pneumonia. Recent experience with the 2009 pandemic influenza A (H1N1) infection showed that critical illness was associated with severe hypoxemia and that multisystem organ failure occurred rapidly after hospital admission and mostly in young adults and pregnant patients.¹⁰⁴

Unusual etiologic organisms should be considered, especially in patients who have epidemiologic risk factors for specific pathogens, as discussed earlier. In addition, certain “modifying factors” may be present that increase the likelihood of CAP caused by certain pathogens.² Thus, the risk factors for DRSP include β -lactam therapy in the past 3 months, alcoholism, age older than 65 years, immune suppression, multiple medical comorbid conditions, and contact with a child in day care.⁹⁴ Risk factors for gram-negative infections include residence in a nursing home, underlying cardiopulmonary disease, multiple medical comorbid conditions, probable aspiration, recent hospitalization, and recent antibiotic therapy. Many of these patients who are at risk for gram-negative infections would now be reclassified as having HCAP.^{2,105}

Some ICU patients are at risk for pseudomonal infection, although others are not, and the risk factors for *P. aeruginosa* infection are structural lung disease (bronchiectasis), corticosteroid therapy (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, previous hospitalization, and malnutrition.² Although aspiration has often been considered a risk factor for anaerobic infection, a study of severe CAP in

Figure 42.2 Computed tomography (CT) scan of the chest of a 25-year-old male admitted with right-sided pleuritic pain after recent influenza infection, showing empyema (A). A repeat CT scan after video-assisted thoracotomy showing intraparenchymal necrosis (B). Tissue culture grew community-acquired methicillin-resistant *Staphylococcus aureus*. Patient was treated with linezolid and had complete resolution of the infiltrate in a 1-month period.

elderly patients with aspiration risk factors found that this population was very likely to have gram-negative infection, and that, using sensitive microbiologic methods, anaerobes were uncommon.¹⁰⁶ Previous studies looking at microbiologic causes in patients admitted with CAP to the ICU have shown wide variation in the results, with a limitation being that not all microbiologic tests were applied systematically for all patients. A recent prospective observational study by Cillóniz and coworkers on 362 consecutive adult patients with CAP admitted to the ICU within 24 hours of presentation reported that 11% of all cases were polymicrobial, with *S. pneumoniae*, respiratory viruses, and *P. aeruginosa* being the commonest isolated pathogens.¹⁰⁷ Other studies have also shown a high frequency of multiple pathogens, including a mixture of bacterial and “atypical” pathogens, which may explain why most patients with severe CAP need to be treated empirically for both groups of organisms. Chronic respiratory disease and ARDS criteria were independent predictors of polymicrobial causes and inappropriate initial antimicrobial treatment was more frequent in the polymicrobial infection group compared with the monomicrobial infection group (39% vs. 10%, $P < 0.001$).

NOSOCOMIAL PNEUMONIA

All patients with this illness are at risk for infection with a group of bacteria referred to as “core pathogens,” which include pneumococcus, *H. influenzae*, MSSA, and nonresistant gram-negative organisms (*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., and *Serratia marcescens*). In addition, some patients are also at risk for infection with other organisms, depending on the presence of risk factors such as prolonged hospitalization (≥ 5 days), prior antibiotic therapy, recent hospitalization (within 90 days), recent antibiotic therapy, residence in a nursing home, or need for chronic care outside the hospital.^{2,60} Patients with these risk factors can possibly be infected with MDR gram-positive and gram-negative organisms including MRSA, *P. aeruginosa* and *Acinetobacter* spp. Recognition of the multiple risk factors associated with these resistant pathogens has made it clear that patients with either early-onset or late-onset nosocomial pneumonia can be infected with MDR

organisms. In addition, up to 40% of patients with VAP have polymicrobial infection, involving multiple pathogens.¹⁰⁸ In immunosuppressed patients uncommon pathogens such as *Aspergillus* species, *Candida* species, *L. pneumophila*, *Pneumocystis jiroveci*, *Nocardia* species, and viruses such as cytomegalovirus should be suspected.⁷⁴

Most data on nosocomial pneumonia bacteriology come from patients with VAP, and the cause in nonventilated patients is presumed to be similar, based on the presence of risk factors for drug-resistant pathogens. In patients with VAP, infection with enteric gram-negative organisms is more common than infection with gram-positive organisms, although the frequency of MRSA infection is increasing in this population, as is infection with *Acinetobacter* spp.¹⁰⁹ In a recent prospective study comparing the clinical and microbiologic characteristics of 315 episodes of ICU-acquired pneumonia (VAP 52% vs. non-VAP 48%) the types of etiologic pathogens and outcome were similar regardless of whether pneumonia is or is not acquired during mechanical ventilation.¹¹⁰

HCAP patients have been included in the nosocomial pneumonia guidelines as being a group at risk for infection with MDR gram-positive and gram-negative organisms.² Although many ICU-admitted patients with this illness are infected with these organisms, one study of nursing home patients requiring mechanical ventilation for severe pneumonia showed that these organisms were not present if the patient with severe pneumonia had not received antibiotics in the preceding 6 months and was also of a good functional status (as defined by activities of daily living).¹¹¹ In approaching the bacteriology of nosocomial pneumonia, it is important to recognize that each hospital, and each ICU within a given hospital, can have its own unique flora and antibiotic susceptibility patterns, and thus therapy needs to be adapted to the organisms in a given institution, which can change over time.¹¹² In addition, it is especially important to know this information because antibiotic resistance is a common factor contributing to initially inappropriate empiric antibiotic therapy. Choosing the wrong empiric therapy has been a particular problem for organisms such as *P. aeruginosa*, *Acinetobacter* spp., and MRSA.⁵³ These highly resistant organisms can be present in as many as 60% of patients who

develop VAP after at least 7 days of ventilation and who have also received prior antibiotic therapy.^{2,60}

ISOLATION OF PATIENTS WITH PNEUMONIA

Patients with certain suspected pathogens should be placed in respiratory isolation to protect both the staff and other patients from infection with these organisms. This practice includes primarily airborne pathogens that spread via the aerosol route and includes any patient who is suspected of having tuberculosis, influenza, respiratory syncytial virus (RSV), or any other epidemic viral infection. Tuberculosis should be considered in any patient with a history of a preceding indolent pneumonia, and in those with severe pneumonia and a history of human immunodeficiency virus (HIV) infection or recent immigration from endemic areas of infection. Patients with MRSA and highly resistant gram-negative infections may need gown, glove, and mask precautions to avoid spread of these difficult-to-treat bacteria.

DIAGNOSTIC ISSUES

GENERAL CONSIDERATIONS

Therapy of severe pneumonia should be started empirically, and laboratory and imaging studies should be done to corroborate the diagnosis and identify the etiologic agent when possible. A specific causal diagnosis is obtained in less than 50% of patients with CAP and the major focus of diagnostic testing is to assess the severity of illness and allow early identification of pneumonia-related complications.¹⁴ However, in most cases of VAP an etiologic agent can be demonstrated, but the presence of a positive culture cannot reliably distinguish infection from colonization.

RADIOGRAPHIC EVALUATION

In all forms of pneumonia, a chest radiograph is used to identify the presence of a lung infiltrate, but in some clinical settings, especially in suspected VAP, there can be noninfectious causes for the radiographic abnormality. A chest radiograph is used to identify complicated and severe illness, such as multilobar infiltrates, cavitation, or a loculated pleural effusion (suggesting an empyema). Chest radiographic patterns are generally not useful for identifying the cause of CAP, although hematogenous dissemination will have bilateral peripheral infiltrates, and aspiration most commonly involves the superior segment of the right lower lobe or posterior segment of the right upper lobe. Findings such as pleural effusion (pneumococcus, *H. influenzae*, *M. pneumoniae*, pyogenic streptococci) and cavitation (*P. aeruginosa*, *S. aureus*, anaerobes, MRSA, tuberculosis) can suggest certain groups of organisms. The chest radiograph may be suboptimal in patients with early infection, severe granulocytopenia, and bullous emphysema and in obese patients. In those instances, it is reasonable to repeat a chest radiograph in 24 to 48 hours.¹⁹ A computed tomography (CT) scan of the chest has better sensitivity in diagnosing an infiltrate (Fig. 42.3), but routine CT scan has not been shown to be associated with improved outcomes. Thin-section CT cannot reliably distinguish bacterial pneumonias from other causes, especially in patients with

Figure 42.3 A 30-year-old male sanitation worker with severe community-acquired pneumonia in the right lung. He was treated with ceftriaxone and moxifloxacin with clinical resolution of symptoms.

underlying lung diseases or immunocompromised conditions except in cases of *Pneumocystis pneumonia*, which has a characteristic pattern.^{113,114} Chest ultrasound is progressively being used to identify the safe site for sampling of the pleural fluid. In the ICU, radiographs are often done at the bedside, and are of such poor quality that pneumonia may be missed or confused with other diagnoses.

ROUTINE LABORATORY TESTS

A complete blood count, chemistry panel, and arterial blood gas analysis are necessary for all patients admitted to the ICU. Leukopenia is seen in patients with severe pneumonia and sepsis caused by pneumococcus or by gram-negative organisms. Both leukocytosis and leukopenia are associated with poor prognosis in patients with CAP¹⁹ and with thrombocytosis and thrombocytopenia.¹¹⁵ Hyponatremia (serum sodium <130 mEq/L) on admission is associated with poor outcome in CAP patients.¹¹⁶ Elevated liver function tests can be seen in a variety of viral and bacterial pneumonias secondary to atypical agents such as *Legionella* spp. and *Mycoplasma* spp., Q fever, tularemia, and psittacosis, as well as in pneumococcal infection.

BLOOD CULTURE

The ATS/IDSA 2007 guidelines recommend that patients with severe CAP and patients with other risk factors, listed later, should have two sets of blood cultures. These results are more likely to be positive if the patient has not received antibiotics at the time of sampling or has any of the following risk factors: underlying liver disease, systolic blood pressure less than 90 mm Hg, fever less than 35°C or greater than 40°C, pulse greater than 125 beats/minute, BUN greater than 10.71 mmol/L (30 mg/dL), serum sodium less than 130 mmol, and leukocyte count less than 5000 or

greater than 20,000 cells/mL.¹¹⁷ Blood cultures should also be considered in patients with asplenia, cavitary infiltrates, or a history of ongoing alcohol abuse. The presence of bacteremia may not worsen prognosis but does allow identification of drug-resistant organisms, and most positive blood cultures in CAP reveal pneumococcus. However, in nosocomial pneumonia, the presence of bacteremia does not necessarily mean pneumonia, and some other extrapulmonary source of infection should be ruled out, especially if the organism present in the blood culture is different from the one in the respiratory tract. In a recent prospective, multicenter trial involving 689 patients with nosocomial pneumonia, a positive blood culture was associated with higher mortality rate (57.1% vs. 33%, $P < 0.001$) and a prolonged length of ICU stay compared to nonbacteremic patients.⁶¹

SPUTUM EXAMINATION

Sputum culture should be accompanied by a Gram stain to guide interpretation of the culture results but not to focus initial antibiotic therapy. In some situations, Gram stain can be used to broaden initial empiric therapy by enhancing the suspicion for organisms that are not covered in routine empiric therapy (such as *S. aureus* being suggested by the presence of clusters of gram-positive cocci, especially during a time of epidemic influenza). A good specimen contains fewer than 10 squamous epithelial cells and more than 25 polymorphonuclear cells per low-power field. The routine testing of expectorated sputum is not useful in the absence of a helpful Gram stain in patients with CAP. In ventilated patients the presence of pathogenic organisms in sputum culture is not diagnostic, because this finding cannot separate oropharyngeal and tracheobronchial colonization from parenchymal lung infection. In addition, some ventilated patients can have VAT, an illness with all the clinical features of pneumonia, but with no new lung infiltrate, and this illness may require antibiotic therapy and involve the same pathogens, present in high concentrations, as are present in VAP.²

INVASIVE CULTURES

Bronchoscopy is not indicated as a routine diagnostic test, but may be needed in some patients with severe forms of CAP to establish an etiologic diagnosis. In these patients, the results of diagnostic testing can often be used to focus the initially broad-spectrum empiric therapy to a simpler regimen.¹¹⁸ In patients with HAP the sputum culture is often not reliable, and in an effort to make the diagnosis more secure, and to avoid the treatment of colonization and not infection, some investigators have used quantitative sampling of lower respiratory secretions collected either bronchoscopically (bronchoalveolar lavage, protected specimen brush) or nonbronchoscopically (endotracheal aspirate, nonbronchoscopic catheter lavage) in patients with suspected VAP. When quantitative cultures are collected, the presence of pneumonia is defined by the growth of bacteria above a predefined threshold concentration.^{119,120} Although the results can guide therapy decisions, most clinicians use antibiotic therapy, regardless of quantitative culture data, in patients who have clinical signs of sepsis and suspected pneumonia. Regardless of whether quantitative cultures are used, all patients with suspected nosocomial pneumonia

should have a lower respiratory tract culture collected prior to the start of antibiotic therapy. If this is not a quantitative culture, then a sputum or tracheal aspirate should be obtained and the findings reported “semiquantitatively” as light, moderate, or heavy growth of bacteria.^{2,120} Unfortunately, a negative culture is difficult to interpret if the patient has had initiation or change in antibiotic therapy in the preceding 72 hours. If, however, either a quantitative or semiquantitative culture is negative, or does not show a highly resistant pathogen, and antibiotics have not been changed in the past 72 hours, then the therapy can often be stopped or focused to a narrower spectrum.^{2,121} A number of studies have examined the ability of quantitative cultures to impact outcome in VAP, and in general, although results are conflicting, there is no consistent evidence that they improve patient outcome or lead to more de-escalation of antibiotics.¹²²

URINARY ANTIGEN, SEROLOGIC, AND POLYMERASE CHAIN REACTION TESTING

Routine serologic testing is not recommended, and a serologic diagnosis of a specific pathogen is based on acute and convalescent blood serologic examinations showing a fourfold increase in titers. This type of testing is used for epidemiologic diagnosis of atypical agents such as *C. pneumoniae*, *C. psittaci*, *Coxiella burnetii* (Q fever), and *M. pneumoniae*. However, in patients with severe illness, the diagnosis of *Legionella* infection can be made by urinary antigen testing, which is the test that is most likely to be positive at the time of admission, but a test that is specific only for serogroup I infection.^{19,123} Examination of concentrated urine for pneumococcal antigen may also be valuable. Urinary pneumococcal antigen has a sensitivity of 50% to 80% and specificity of over 90%. False-positive tests are seen in patients who had pneumonia within the previous 3 months. Polymerase chain reaction (PCR) assays are used for the detection of viruses (as was the case in the H1N1 epidemic) and other agents such as *M. tuberculosis*. Direct immunofluorescence or enzyme immunoassay is used for detection of viral antigens such as influenza, parainfluenza, RSV, and adenovirus. The impact of a positive test on management is still unclear, but a negative test is valuable in directing a focused antibiotic regimen.

ROLE OF BIOMARKERS

SERUM BIOMARKERS

Inflammatory biomarkers like CRP, PCT, midregional pro-adrenomedullin, midregional proatrial natriuretic peptide (MR-proANP), proarginin-vasopressin, proendothelin-1, and the interleukins have been used to distinguish bacterial infection from viral infection. Ramirez and associates showed that inflammatory biomarkers like PCT, CRP, tumor necrosis factor- α , and interleukin 6 levels were higher in patients admitted to the ICU, including those with delayed ICU admission, than those not needing ICU care.²⁸

PCT is a “hormokine” (hormone with cytokine-like behavior), a peptide precursor of the hormone calcitonin, with a half-life of 25 to 30 hours. It is produced in response to bacterial microbial toxins and inhibited by virus-related cytokines. In patients with CAP, PCT levels on admission correlate with disease severity and identify high-risk patients

with similar accuracy as the CURB-65 score and with a higher prognostic accuracy compared with CRP and leukocyte count.^{27,124} In fact, if the PCT level on admission is low, prognosis is good, regardless of PSI class or CURB-65 score.¹²⁴ Serum levels tend to be high in patients with severe bacteremic CAP, and serial measurements help guide the duration of antibiotic therapy.¹²⁵ Luyt and colleagues reported that PCT levels decreased during the clinical course of VAP but were significantly higher from day 1 to day 7 in patients with unfavorable outcomes.¹²⁶ A recent prospective study by Bloos and colleagues on 175 patients with severe pneumonia admitted to the ICU (CAP, HAP, and VAP, equally distributed) showed that PCT levels were higher and remained persistently elevated in nonsurvivors compared to survivors.¹²⁷ The initial and maximum PCT levels correlated with maximum SOFA score and the initial PCT levels were higher in CAP than in VAP patients (median; 2.4 vs. 0.7 ng/mL, $P < 0.001$) but not significantly different from HAP patients (2.2 ng/mL), but patients with CAP were more severely ill, with a higher APACHE II score. In another multicenter, prospective, parallel-group study in the ICU setting, patients were randomly assigned in a 1:1 ratio to PCT-guided ($n = 311$ patients) or control ($n = 319$) groups and antibiotic regimens were instituted based on a protocol with predefined cutoff levels of PCT. There was no difference in mortality rate between PCT group and control group at day 28 (21.2% vs. 20.4%),¹⁰ but patients in the PCT group had significantly more days without antibiotics than those in the control group (14.3 days vs. 11.6 days, $P < 0.0001$). This supports earlier data that a drop in PCT levels could be used to define when antibiotic treatment can be safely withdrawn.⁹

OPEN LUNG BIOPSY

This procedure is rarely needed unless there is persistence of infiltrates on imaging and suspicion for atypical organisms (such as *Aspergillus*, cytomegalovirus, *Cryptococcus* spp., *Nocardia*, and *Toxoplasma gondii*) is high in an immunocompromised host with progressive disease not responding to standard treatment regimens. Open lung biopsy is also useful if a pneumonia mimic (inflammatory lung disease, pulmonary hemorrhage, or malignancy) is suspected.

RECOMMENDED TESTING FOR COMMUNITY-ACQUIRED PNEUMONIA

The ATS/IDSA guidelines recommend that all CAP patients admitted to the ICU should have a chest radiograph, blood and lower respiratory tract (sputum, endotracheal aspirate, bronchoalveolar lavage, or bronchoscopic specimen) cultures, and *Legionella* and pneumococcal urine antigen testing. If the patient has a moderate-sized pleural effusion, this should be tapped and the fluid sent for culture and biochemical analysis. Those with a cavitary infiltrate on chest imaging should have fungal cultures and tuberculosis testing performed.

Severity assessment scores such as ATS/IDSA 2007 guidelines or SMART-COP can be used to determine the severity of the disease and serum biomarkers like PCT should be used to guide site of care decisions. In patients with no response to treatment or unrelenting high levels of biomarkers, further imaging or invasive diagnostic methods such as bronchoscopy and thoracentesis should be performed and an alternate diagnosis other than CAP should be considered. A suggested diagnostic/treatment approach is provided in [Figure 42.4](#).

RECOMMENDED TESTING FOR NOSOCOMIAL PNEUMONIA

Nosocomial pneumonia is diagnosed when a patient has been in the hospital for at least 48 to 72 hours and then develops a new or progressive infiltrate on chest radiograph, accompanied by at least two of the following three: fever, leukocytosis, and purulent sputum. As mentioned, these clinical findings may be sensitive but not specific for infection, and efforts to improve the clinical diagnosis of pneumonia have involved the previously mentioned CPIS.¹²⁸ The CPIS uses six criteria (fever, purulence of sputum, white blood cell count, oxygenation, degree of radiographic abnormality, and presence of pathogens in the sputum), with each scored on a scale from 0 to 2, and pneumonia is diagnosed with a total score of at least 6 (out of a maximum of 12). The CPIS was modified by Singh and coworkers to include radiographic progression in order to improve diagnostic accuracy ([Table 42.1](#)).¹²⁹ The CPIS at 72 hours

Table 42.1 Modified Clinical Pulmonary Infection Score

Sign	0	1	2
Temperature (°C)	36.5-38.4	38.5-38.9	<36 or >39
White blood cell count (cells/μL)	4.0-11.0	<4.0 or >11.0	>500 band forms
Oxygenation (PaO ₂ /FiO ₂)	>240 or ARDS		<240 and no ARDS
Radiographic findings	No infiltrate	Diffuse infiltrate	Localized infiltrate
Radiographic progression	No progression		Radiographic progression after CHF and ARDS excluded
Tracheal secretions	Absence of secretions	Nonpurulent	Purulent
Culture of tracheal aspirate	Pathogenic bacteria cultured: rare or light quantity or no growth	Pathogenic bacteria cultured: moderate or heavy quantity	Same pathogenic bacteria as on original Gram stain: add 1 point

ARDS, acute respiratory syndrome; CHF, congestive heart failure.

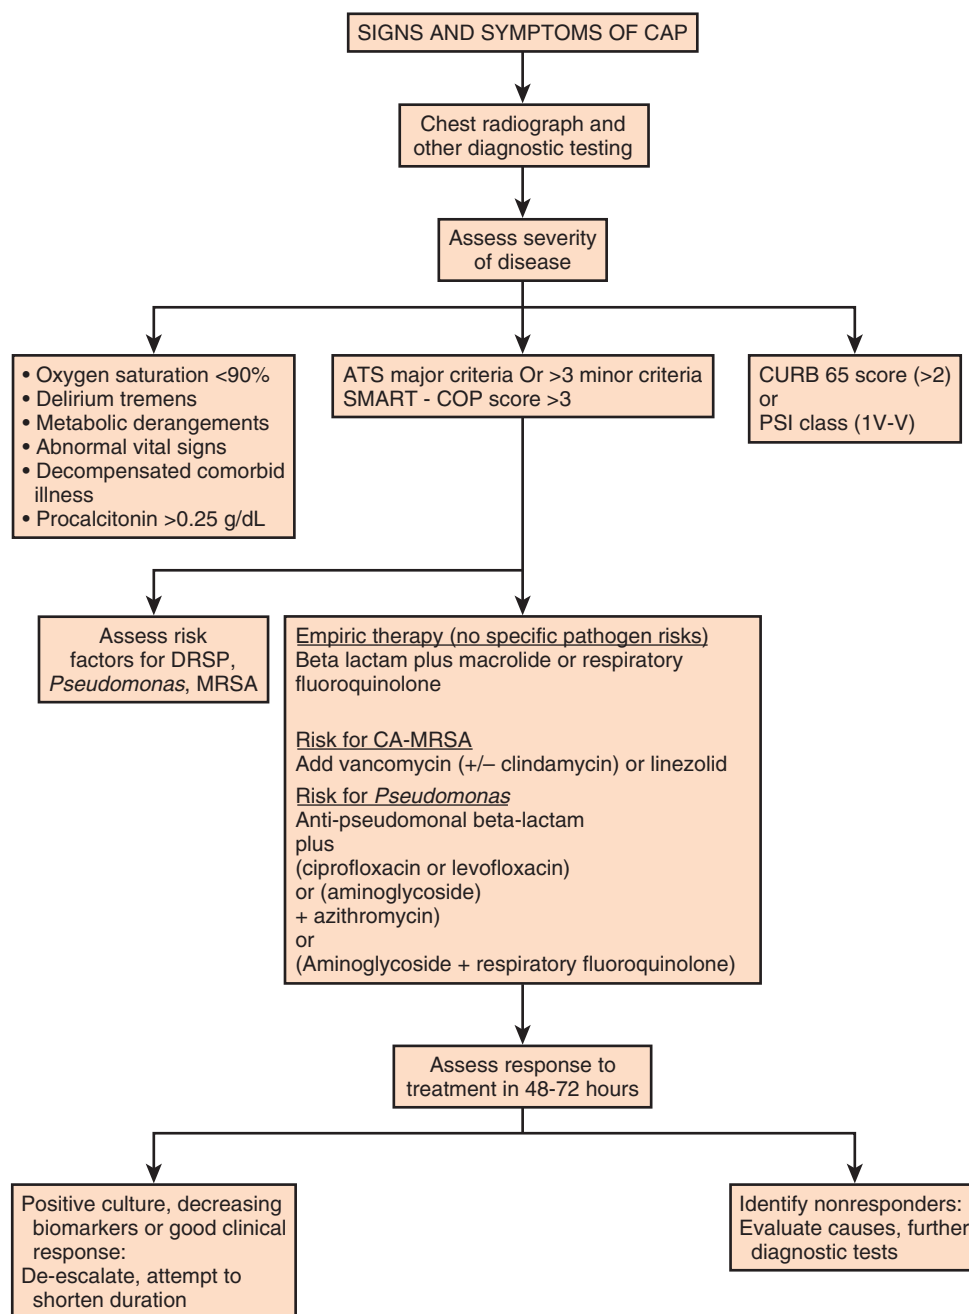

Figure 42.4 A suggested algorithm for diagnosis and management of community-acquired pneumonia in the intensive care unit setting.

was calculated on the basis of all seven variables and took into consideration the progression of the infiltrate and culture results of the tracheal aspirate specimen. A CPIS greater than 6 at baseline and at 72 hours was considered suggestive of pneumonia and indicated the need for a full course of antibiotic therapy. However, subsequent studies showed that CPIS has a low sensitivity and specificity for diagnosing VAP compared to quantitative cultures of bronchoalveolar lavage fluid, with considerable interobserver variability.¹³⁰ Thus, the use of CPIS remains controversial and has been most successfully used in guiding treatment decisions for patients with a low likelihood of VAP and in guiding the duration of therapy and defining the response to treatment.^{42,131}

Many studies have documented that VAP is diagnosed more often clinically than can be confirmed microbiologically, and the diagnosis is further obscured by the fact that most mechanically ventilated patients are colonized by enteric gram-negative bacteria, and thus the finding of potential pathogens in the sputum has limited diagnostic value. Many patients with suspected nosocomial pneumonia can have other diagnoses, which can be suggested by the rapidity of the clinical response and by the nature of the clinical findings. These diagnoses include atelectasis and congestive heart failure (very rapid clinical resolution), or in the case of a lack of response to therapy, inflammatory lung diseases, extrapulmonary infection (sinusitis, central-line infection, intra-abdominal infection), or the presence of an

unusual or drug-resistant pathogen. The ATS/IDSA guidelines for nosocomial pneumonia have recommended that all patients have a lower respiratory tract sample collected prior to starting therapy and that the technique and culture method be one that the clinician is expert at performing and interpreting. Lower respiratory tract cultures can be obtained bronchoscopically or nonbronchoscopically and can be cultured quantitatively or semiquantitatively. A suggested algorithm for diagnosis and treatment of nosocomial pneumonia is provided in Figure 42.5.

THERAPY

GENERAL CONSIDERATIONS

Timely initiation of appropriate antibiotics has significant mortality benefit for both severe CAP and VAP patients. The ATS and IDSA have developed algorithms for initial empiric therapy, based on the most likely etiologic pathogens in a given clinical setting.^{2,19} If diagnostic testing reveals a specific etiologic pathogen, then therapy can be focused on

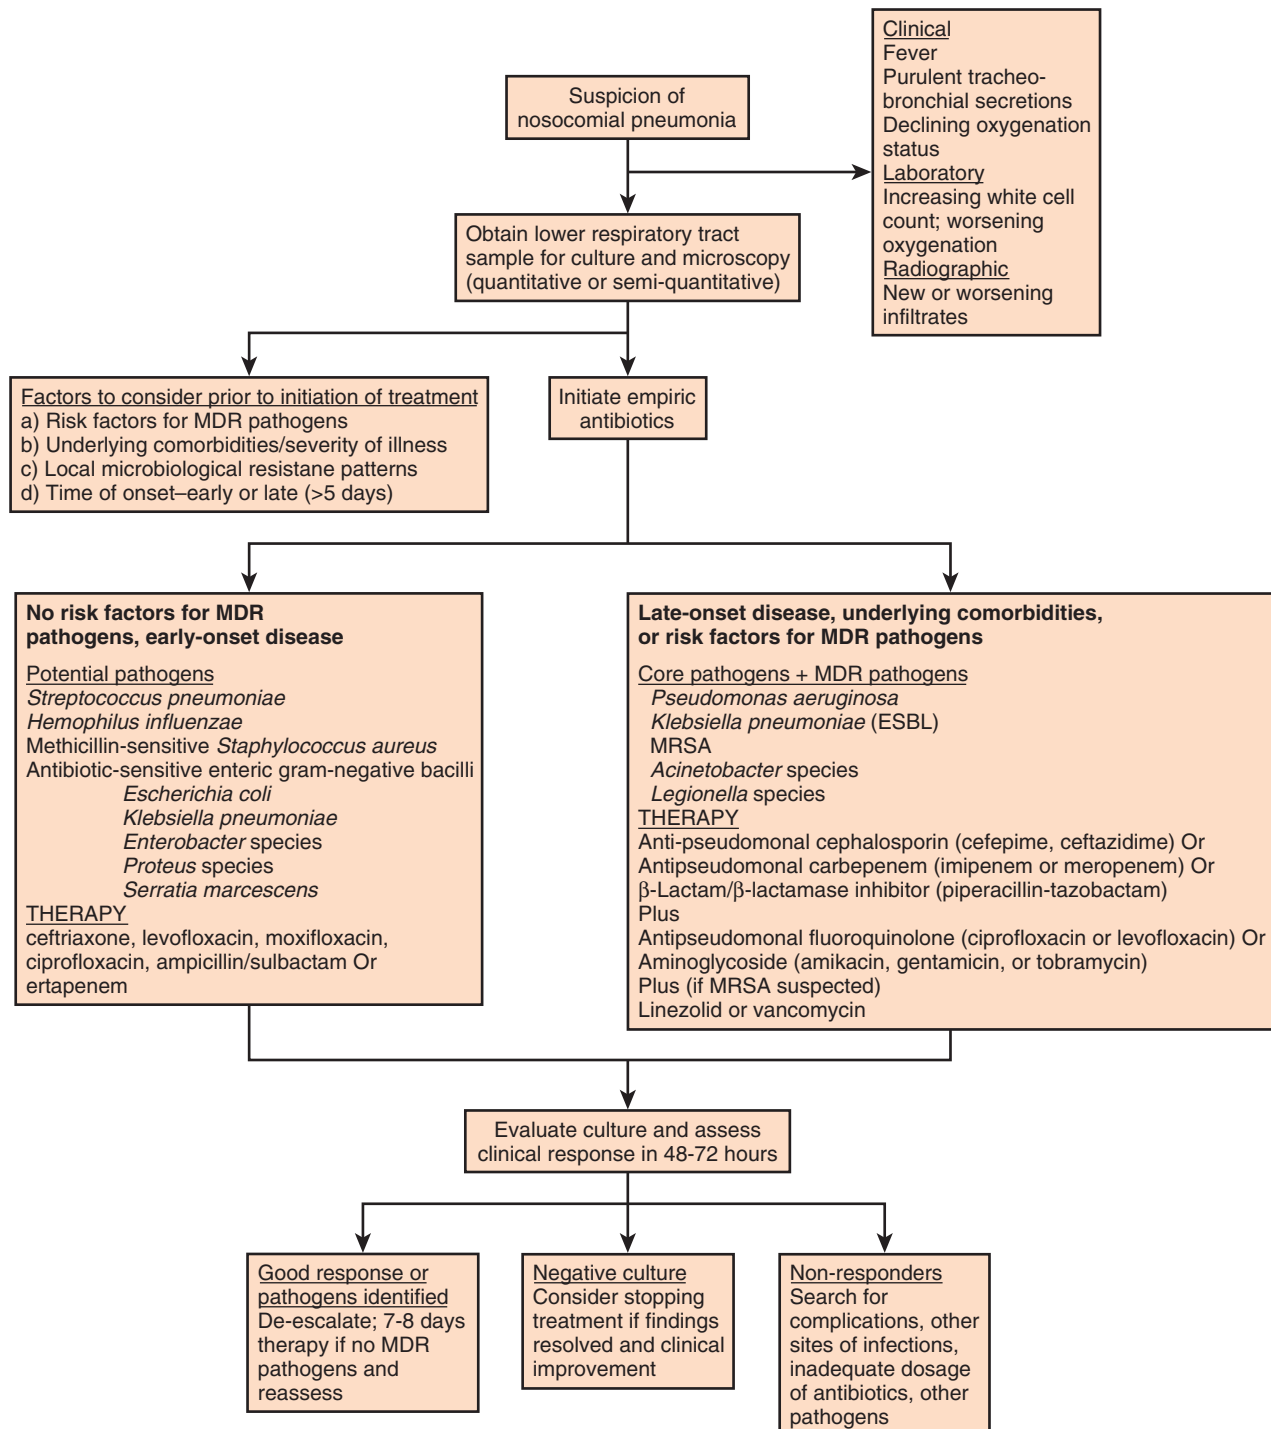

Figure 42.5 A suggested algorithm for the diagnosis and treatment of nosocomial pneumonia.

those results. De-escalation of antibiotics is valuable in the management of VAP because most patients are at risk for infection with MDR pathogens, requiring empiric broad-spectrum antibiotics, and this can lead to antibiotic overuse and further development of resistance if therapy is not adjusted once culture and clinical response data become available.⁶⁴

MICROBIAL RESISTANCE

Patients in the ICU are at a high risk of developing infection, which is often due to antibiotic-resistant pathogens. The incidence of resistance is related to several factors: (1) induction of resistant strains (e.g., emergence of resistance during treatment because of the selection of new mutations), (2) selection of resistant strains (e.g., antimicrobial treatment may select and favor overgrowth of preexisting resistant flora), (3) introduction of resistant strains (e.g., cross-transmission from other patients or health care workers), and (4) dissemination of resistant strains (e.g., suboptimal infection control).¹³² There is growing concern about MDR pathogens in the United States, belonging to the group of “ESKAPE” organisms (*Enterococcus faecium*, *S. aureus*, *K. pneumoniae*, *Acinetobacter baumannii*, *P. aeruginosa*, and *Enterobacter* species).^{133,134} A recent prospective interventional study evaluated the effect of antimicrobial diversity on resistance caused by the ESKAPE pathogens in patients with VAP. The study was conducted over 44 months and examined three different antimicrobial strategies implemented consecutively: (1) a patient-specific period, when therapy was based on preexisting risk factors; (2) a 24-month scheduling period, in which antipseudomonal β -lactams were selected and prioritized quarterly during the first 12 months (prioritization periods) and restricted during the next 12 months (restriction periods); and (3) a mixing period over the next 10 months. VAP due to the ESKAPE pathogens increased significantly during scheduling compared with patient-specific and mixing periods (RR, 2.67 and 3.84, respectively).¹³⁵ During the periods in which a diverse prescription pattern was implemented, there was a lower incidence of VAP due to ESKAPE organisms and the authors concluded that antibiotic strategies promoting diversity may prevent the emergence of MDR organisms.

ANTIBIOTIC CONSIDERATIONS

All patients with severe pneumonia treated in the ICU should receive initial empiric combination therapy. The rationale for this approach is to provide broad antimicrobial coverage to assure appropriate therapy. In addition, there has been the hope that, in the therapy of nosocomial pneumonia, combination therapy could prevent the emergence of resistance during therapy and potentially provide synergistic activity if a β -lactam antibiotic is combined with an aminoglycoside (for *P. aeruginosa* pneumonia). However, only with bacteremic *P. aeruginosa* pneumonia has combination therapy (generally with an aminoglycoside and a β -lactam) been shown to be superior to monotherapy.^{136,137} In the absence of bacteremia, an older meta analysis found no therapeutic benefit to adding an aminoglycoside to a β -lactam in critically ill patients, but the impact on

appropriateness of therapy was not evaluated.¹³⁷ Currently, with the high prevalence of MDR pathogens in nosocomial pneumonia, combination therapy increases the likelihood of appropriate therapy, compared to monotherapy. In fact, in the Canadian Clinical Trials group study of VAP, even though combination therapy did not reduce mortality rates, compared to monotherapy, it led to appropriate therapy 84% of the time when MDR pathogens were present, compared to 11% of the time when these organisms were treated with monotherapy.¹³⁸

One practical problem to using aminoglycosides is that they have a narrow therapeutic-to-toxic ratio and a high incidence of nephrotoxicity, particularly in elderly patients. When these drugs are used, it is important to achieve high peak serum levels to optimize efficacy, but to also avoid elevated trough levels, which correlate with toxicity. When peak serum levels have been monitored, levels of more than 7 $\mu\text{g/mL}$ for gentamicin and tobramycin and more than 28 $\mu\text{g/mL}$ for amikacin have been associated with more favorable outcomes.¹³⁹ One other limitation of aminoglycosides is their relatively poor penetration into bronchial secretions, achieving only 40% of the serum concentrations in the lung. In addition, antimicrobial activity is reduced at the low pH levels that are common in the bronchial secretions of patients with pneumonia.¹⁴⁰ To address some of these concerns, it has now become standard to administer aminoglycosides by combining the total 24-hour dose into a single dose, rather than in divided doses. This approach is theoretically possible because bactericidal activity of aminoglycosides is optimized by high peak concentrations, and once-daily dosing relies on the prolonged postantibiotic effect of aminoglycosides. This approach might not only improve efficacy but also reduce (or at least not increase) toxicity because of low trough levels, and reduce the need for monitoring of serum levels. In one meta-analysis, this approach proved to have little advantage with regard to efficacy or safety.¹⁴¹ However, once-daily dosing is now standard, and optimizing drug pharmacokinetics and pharmacodynamics is important in ICU patients, and this goal can be achieved by using maximal doses of antibiotics while choosing proper drug delivery schemes. This means using once-daily dosing of aminoglycosides, and prolonged infusion of high-dose β -lactams, the latter taking advantage of the time-dependent killing of β -lactams, in contrast to the concentration-dependent killing by aminoglycosides. In one study that used an optimized approach to antibiotic dosing and delivery versus standard therapy, infection-related mortality rate was reduced (8.5% vs. 21.6%).¹⁴²

Initial empiric therapy of CAP treated in the ICU should also be with a combination of agents, usually directed at bacterial pathogens and atypical pathogens. In severe CAP, even with documented pneumococcal bacteremia, dual therapy is associated with reduced mortality rate compared to monotherapy. In the selection of a second agent, a macrolide may be preferred over a quinolone, possibly due to its anti-inflammatory properties, with the main exception being a preference for quinolones if *Legionella* is suspected.

Although initial therapy of severe pneumonia usually requires multiple agents, once culture data are available, as part of a de-escalation strategy, monotherapy can often be used. Even patients with severe nosocomial pneumonia

can be converted to monotherapy, provided that certain high-risk organisms are absent (*P. aeruginosa*, *Acinetobacter* spp., and MRSA), but the antibiotics that have been effective as monotherapy for severe VAP include imipenem, meropenem, doripenem, cefepime, ciprofloxacin, high-dose levofloxacin (750 mg daily), and piperacillin/tazobactam.^{2,121,143-147} Circumstances in which monotherapy should not be used include the following: (1) in any patient with severe CAP, in which the efficacy of this approach has not been demonstrated; (2) in suspected or documented bacteremic infection with *P. aeruginosa*; (3) in the empiric therapy of VAP if the patient has risk factors for infection with MDR pathogens; and (4) if the patient has nosocomial pneumonia and both *S. aureus* and *P. aeruginosa* are identified in culture as the etiologic pathogens. Monotherapy of nosocomial infection should never be attempted with a third-generation cephalosporin because of the possibility of emergence of resistance during therapy as a result of production of chromosomal β -lactamases by the Enterobacteriaceae group of organisms.²

If *P. aeruginosa* is the target organism, then antibiotics with efficacy against this pathogen are needed. Antipseudomonal β -lactam antibiotics include the penicillins—piperacillin, azlocillin, mezlocillin, ticarcillin, and carbenicillin; the third-generation cephalosporins ceftazidime and cefoperazone; the fourth-generation cephalosporin cefepime; the carbapenems imipenem, doripenem, and meropenem; the monobactam aztreonam (which can be used in the penicillin-allergic patient); and the β -lactam/ β -lactamase inhibitor combinations ticarcillin/clavulanate and piperacillin/tazobactam. Other antipseudomonal agents include the quinolone ciprofloxacin, high-dose levofloxacin (750 mg/day), and the aminoglycosides (amikacin, gentamicin, tobramycin).

In patients with suspected MRSA pneumonia, therapy should be with either vancomycin or linezolid (a bacteriostatic, oxazolidinone antibiotic). Early subgroup analysis of two prospective randomized, controlled trials suggested that linezolid led to higher cure and survival rates, compared to vancomycin in patients with documented MRSA VAP.¹⁴⁸ A subsequent prospective study of patients with suspected MRSA VAP, randomized to receive either linezolid, 600 mg, or vancomycin, 1 g every 12 hours, showed trends in favor of linezolid for bacteriologic cure and survival that were not statistically significant.¹⁴⁹ The comparison between linezolid and vancomycin has been evaluated by several meta analyses, which showed no definitive difference, except for a trend in favor of linezolid for clinical success.¹⁵⁰ Recently, a large multicenter trial comparing linezolid to optimally dosed vancomycin was completed, including nearly 400 patients with documented MRSA VAP and HCAP. In that trial, linezolid led to a significantly higher rate of clinical response than vancomycin, but no difference in mortality rate.¹⁵¹ In the study, vancomycin caused more nephrotoxicity, a problem that has been increasingly common when trough levels are pushed above 15 mg/L. Telavancin is another agent that has been studied in MRSA VAP, but when compared to vancomycin, it had no clear advantage and a similar rate of nephrotoxicity but did lead to better clinical responses when MRSA was intermediately sensitive to vancomycin, with MIC values higher than 1 mg/L.¹⁵² In fact, recent studies have shown that the frequency of MRSA with

these higher MIC values is increasing, and this is further challenging the efficacy of vancomycin.¹⁵³ Tigecycline has efficacy against MRSA, but has not shown efficacy in VAP, although daptomycin is active against MRSA when it causes bacteremia but is inactivated by pulmonary surfactant, and thus cannot be used to treat pneumonia.

Acinetobacter spp. are inherently resistant to cephalosporins, penicillins, and aminoglycosides.¹⁵⁴ In the past, the most reliable therapy for these agents was a carbapenem, but now resistance to carbapenems is more common, necessitating the use of polymixin B and E (colistin). *Acinetobacter* is sensitive in vitro to tigecycline, but in a clinical trial, tigecycline monotherapy was inferior to imipenem in the therapy of VAP, including when *Acinetobacter* was present, and thus if this agent is used, it is probably best as part of a combination regimen, along with a carbapenem, sulbactam, colistin, or an aminoglycoside.¹⁵⁵

ROLE OF CORTICOSTEROIDS

The fact that inflammatory markers such as IL-6, IL-8, and IL-10 are elevated in patients with severe CAP and decrease in the first few days of appropriate antibiotic therapy favored the possible use of immunomodulators and anti-inflammatory medications such as macrolides, or steroids as an adjunct to reduce the proinflammatory cytokines. One randomized controlled trial of 48 patients compared hydrocortisone infusion (240 mg/day) to placebo, and found that steroid therapy reduced mortality rates, length of stay, and duration of mechanical ventilation.¹⁵⁶ Subsequent studies have not consistently shown benefit for the use of corticosteroids as routine therapy in severe CAP. A meta analysis of available data concluded that there was no definite benefit but also no adverse consequences,¹⁵⁷ although a prospective randomized controlled trial showed a higher frequency of late clinical failure when steroids were used as adjunctive therapy in CAP.¹⁵⁸ Corticosteroids were also used as adjunctive therapy in patients with severe H1N1 pneumonia with ARDS, and were associated with an increased mortality rate, suggesting harm from their use.¹⁵⁹ Given the currently available data, corticosteroids should not be part of routine therapy of severe CAP. In special situations, however, steroids may have value. Patients with pneumonia and pneumococcal meningitis may benefit from adjunctive corticosteroid therapy (dexamethasone) if it is started prior to the initiation of antibiotic therapy, because it may lead to improved long-term neurologic outcomes.^{160,161} Patients with *P. jiroveci* pneumonia also benefit from corticosteroid therapy, if the initial arterial oxygen tension is less than 70 mm Hg, by attenuating some of the inflammation that is induced by antibiotic killing of the organisms. In patients with pneumonia and refractory shock some investigators have considered using corticosteroids to treat relative adrenal insufficiency, but a large prospective randomized trial could not demonstrate benefit.¹⁶²

NONPHARMACOLOGIC MEASURES

Adjunctive therapeutic measures are needed in some patients, including oxygen, chest physiotherapy (if at least 30 mL of sputum daily, and a poor cough response), mucolytic agents, and aerosolized bronchodilators.

COMMUNITY-ACQUIRED PNEUMONIA THERAPY ALGORITHM (SEE FIG. 42.4)

For ICU-admitted CAP patients, initial therapy should be directed at DRSP, *Legionella*, and other atypical pathogens in all patients, and for selected patients, enteric gram-negative and other organisms should also be targeted, based on epidemiologic risk assessment. Therapy falls into two categories, depending on whether the patient is at risk for *P. aeruginosa* (structural lung disease such as bronchiectasis, therapy with broad-spectrum antibiotics for more than 7 days in the last month, use of corticosteroids [more than 10 mg of prednisone daily], malnutrition, or HIV infection). In certain circumstances, such as pneumonia complicating influenza, therapy should also include empiric coverage for *S. aureus* (including MRSA).

MONOTHERAPY VERSUS COMBINATION THERAPY

In all treatment algorithms, no ICU-admitted CAP patient should receive empiric monotherapy, even with a quinolone.⁹⁵ In a study comparing levofloxacin to a β -lactam/quinolone combination, the single-agent regimen was not tested in patients with septic shock and was not optimally effective for those treated with mechanical ventilation.¹⁶³ Rodríguez and colleagues reported in a subset of patients with CAP and shock that combination therapy with either a β -lactam and a macrolide or a β -lactam and a quinolone had a 28-day survival advantage compared to patients receiving monotherapy with a quinolone or a β -lactam alone.¹⁶⁴ In contrast, another prospective observational study of 218 mechanically ventilated patients with CAP found that the use of a macrolide, but not a quinolone, was associated with reduced mortality rate.¹⁶⁵ Several other studies have specifically shown benefit for combination therapy in patients with documented pneumococcal bacteremia. In one study that examined data from 2209 Medicare patients with bacteremic pneumonia, the initial use of antibiotic with atypical pathogen coverage, particularly a macrolide, was independently associated with a decreased 30-day mortality risk (odds ratio [OR] = 0.76; $P = 0.03$).¹⁶⁶ This confirmed earlier data from a prospective study of bacteremic pneumococcal pneumonia patients, showing that combination antibiotic therapy (usually by adding a macrolide antibiotic) was associated with lower 14-day mortality rate compared to monotherapy (23.4 vs. 55.3%, $P = 0.0015$) for patients with severe illness.¹⁶⁷

ATS/IDSA 2007 GUIDELINES

Recommended therapy for severe CAP, in the absence of pseudomonal risk factors, should be with a selected intravenous β -lactam (cefotaxime, ceftriaxone, ertapenem, a β -lactam/ β -lactamase inhibitor combination), combined with either an intravenous macrolide or an intravenous antipneumococcal quinolone (levofloxacin or moxifloxacin). For patients with pseudomonal risk factors, therapy can be with a two-drug regimen, using an antipseudomonal β -lactam (imipenem, meropenem, piperacillin/tazobactam, cefepime) plus ciprofloxacin (the most active antipseudomonal quinolone) or levofloxacin (750 mg daily); or alternatively with a three-drug regimen, using an antipseudomonal β -lactam plus an aminoglycoside plus either an intravenous antipneumococcal quinolone (levofloxacin,

or moxifloxacin) or a macrolide.^{95,168} In patients with bacteremic pneumococcal pneumonia, particularly in those with severe illness, as discussed earlier, dual therapy including a macrolide has been associated with improved outcomes.¹⁶⁷

In patients with risk factors for MRSA, vancomycin (and possibly clindamycin) or linezolid alone should be added to the regimen. Most experts recommend that CA-MRSA be targeted in patients with severe, necrotizing CAP including those with empyema, following a viral illness, particularly influenza. Optimal therapy has not been defined, and vancomycin alone may not be sufficient, and has led to clinical failure, presumably because it is not active against the PVL toxin production that accompanies CA-MRSA. For that reason, it may be necessary to add clindamycin to vancomycin or to use linezolid, because both of these latter agents can inhibit toxin production.¹⁰³

TIMING OF ANTIBIOTICS

In addition to the antibiotic approach to therapy outlined previously, there are several other considerations in the management of severe CAP. These plans include providing the first dose of therapy as soon as possible and providing coverage in all patients for atypical pathogens using either a macrolide or a quinolone in the regimen, based on data that such an approach reduces mortality rate.¹⁶⁹⁻¹⁷¹

DURATION OF TREATMENT

There is little information on the proper duration of therapy in patients with CAP, especially those with severe illness. Even in the presence of pneumococcal bacteremia, short durations of therapy may be possible, with a rapid switch from intravenous to oral therapy in responding patients. Generally, *S. pneumoniae* can be treated for 5 to 7 days if the patient is responding rapidly and has received accurate empiric therapy at the correct dose. The presence of extrapulmonary infection (such as meningitis), and the identification of certain pathogens (such as bacteremic *S. aureus*, and *P. aeruginosa*) may require longer durations of therapy. Identification of *L. pneumophila* pneumonia may require at least 14 days of therapy, depending on severity of illness and host defense impairments, although recent data have shown that quinolone therapy may be the best approach to management and that durations as short as 5 days with levofloxacin 750 mg may be effective.¹⁷² Biomarkers, especially PCT, can be followed serially to guide duration of therapy for severe CAP. Although early studies of PCT did not involve patients with severe pneumonia, one large randomized controlled trial, including 326 ICU patients with CAP, showed that serial measurement of PCT, compared to standard care, led to a reduction in duration of therapy of 3.3 days.¹⁰ The switch to oral therapy, even in severely ill patients, may be facilitated by the use of quinolones, which are highly bioavailable and achieve the same serum levels with oral therapy as with intravenous therapy.

NOSOCOMIAL PNEUMONIA THERAPY ALGORITHM (SEE FIG. 42.5)

In defining therapy for patients with nosocomial pneumonia, it is important to evaluate (a) time of onset of infection, (b) underlying comorbid conditions, (c) severity of

disease—based on scoring systems, and (d) risk factors for MDR pathogens. Antibiotic therapy should be given at the first clinical suspicion of infection, and empiric therapy should be dictated by dividing patients into a group not at risk for MDR pathogens, and a group that is at risk. Those who are not at risk for MDR pathogens include patients with both early onset of infection, and no risks for HCAP such as recent hospitalization, treatment in a health care–associated facility (nursing home, dialysis center, etc.), and no history of recent antibiotic therapy in the past month. Patients with either late-onset infection or the presence of any of the other MDR risk factors are treated empirically for infection with MDR gram-negative and gram-positive pathogens. Not all HCAP patients are at risk for MDR pathogens, and those who are not can receive a narrow-spectrum regimen, similar to that used for CAP. The HCAP patient who is at risk for MDR pathogens is the patient with severe pneumonia and any additional MDR risk such as antibiotic therapy or hospitalization in the past 3 months, poor functional status, and immune suppression. MDR pathogens are not likely in HCAP patients with severe pneumonia who do not have any of these other risks present.¹⁰⁶

CHOOSING THE APPROPRIATE REGIMEN

Patients who have no MDR risks can be treated for the “core pathogens” listed earlier, generally with a monotherapy regimen of a second- or nonpseudomonal third-generation cephalosporin, a β -lactam/ β -lactamase inhibitor combination, ertapenem, or a quinolone (levofloxacin or moxifloxacin).⁹ If the patient is penicillin-allergic, therapy can be with a quinolone or the combination of clindamycin and aztreonam. As mentioned earlier HCAP patients without MDR risks should also receive monotherapy, an approach that has been successful in this well-defined subgroup of individuals.

Patients at risk for MDR pathogens generally require combination therapy, rather than monotherapy, which is effective against the core pathogens, as well as MDR gram-negative organisms and MRSA. As discussed, combination therapy is necessary for this population because it provides broad-spectrum coverage, thereby minimizing the chance of initially inappropriate therapy.¹⁷³ The empiric therapy for patients at risk for MDR pathogens should include an aminoglycoside or quinolone (ciprofloxacin or high-dose levofloxacin) plus an antipseudomonal β -lactam (imipenem, meropenem, doripenem, piperacillin/tazobactam, aztreonam, or cefepime). Because most patients are at risk for a second ICU-acquired infection, it may be prudent to use an aminoglycoside for the first episode of infection, reserving the quinolone for any subsequent infection, because of concern about quinolone induction of multidrug resistance, which could limit subsequent therapy options.¹⁷⁴ In addition, the efficacy of quinolones against MDR gram-negative organisms in the ICU is not as good as in years past, making an aminoglycoside a more reliable empiric choice in most hospitals. In one study, when a quinolone was added to the best β -lactams, the combination was only minimally better than monotherapy, covering less than 85% of the gram-negative organisms, but when amikacin was added to the same β -lactams, coverage was over 95%.¹⁷⁵ Empiric therapy of MRSA is needed when the patient is at high risk for this pathogen because of a tracheal aspirate Gram stain showing

gram-positive organisms or because of other risk factors. In this setting, a third drug should be added, either linezolid or vancomycin, but as discussed previously, recent data have suggested an advantage for linezolid in patients with documented MRSA VAP, because of higher clinical efficacy and a lower risk of nephrotoxicity.¹⁵¹ When *Acinetobacter* spp. or ESBL-producing Enterobacteriaceae are present, therapy should be with a carbapenem if the pathogen is sensitive; if not, then therapy could be with colistin, or a combination of agents, including tigecycline with sulbactam, colistin, or an aminoglycoside.

In the selection of an empiric therapy regimen, it is also necessary to know which antibiotic the patient has recently received (within the past 14 days) and to choose an agent that is in a different class, because repeated use of the same class of antibiotic may drive resistance to that class, especially if the pathogen is *P. aeruginosa*.¹⁷⁶ Similar findings have been made for patients with bacteremic pneumococcal pneumonia and CAP, and repeat use of an agent within 3 months may mean that the patient is being treated with an agent to which pneumococcus is more likely to be resistant.¹⁷⁷ In addition, the recent use of quinolones may present a particular problem, because in the ICU, recent quinolone therapy may predispose to not only quinolone-resistant organisms but also to infection with MDR pathogens, extended-spectrum β -lactamase-producing gram-negative organisms, and MRSA.¹⁷⁸ For all patients with VAP, it is important to use the correct dose of antibiotic, and the recommended doses for patients with normal renal function appear in [Box 42.7](#).

Although it is possible to use risk factors to identify the patient who is likely to be infected with MDR pathogens, it is important to realize that each hospital, and each ICU has its own unique organisms, and patterns of antimicrobial resistance, and that these patterns change over time. Therefore, it is necessary to monitor local patterns of resistance and to choose empiric therapy that is likely to be effective in a given clinical setting.¹¹² One other therapeutic concept that has been considered is that of “antibiotic rotation,” an idea that means that the standard empiric regimens are intentionally varied over time to expose bacteria to different antibiotics and potentially minimize the selection pressure for resistance. In some studies, this approach has been effective in reducing the incidence of infection with resistant organisms.¹⁷⁹ One of the limitations of antibiotic rotation is that it may mean the use of the same regimen repeatedly in the same patient, and this may itself be a risk factor for selecting for resistance.¹⁸⁰ Currently, this approach is not widely used or recommended.

DURATION OF TREATMENT

There are limited data regarding the optimal duration of treatment for nosocomial pneumonia. Most patients in the past have received 10 to 14 days of treatment, although those infected with non-lactose-fermenting organisms such as *P. aeruginosa* have received 14 to 21 days of treatment.⁷⁴ If the lower respiratory tract cultures are negative, it may be possible to stop therapy (especially if an alternative diagnosis is suspected) or to shorten the duration of therapy. In addition, if cultures show that the initial empiric regimen was appropriate, and if the patient has a good clinical response (reflected by a drop in the CPIS or decreased

Box 42.7 Recommended Doses of Commonly Used Antibiotics for Critically Ill Patients

β-Lactams

Cefepime 1-2 g q8-12h
 Ceftazidime 2 g q8h
 Ceftriaxone 2 g once daily
 Imipenem 1 g q8h or 500 mg q6h; can give by prolonged infusion
 Meropenem 1 g q6-8h, but can use up to 2 g q6-8h by prolonged infusion
 Doripenem 500 mg q8h, by 1- or 4-hour infusion (not approved for pneumonia)
 Piperacillin-tazobactam 4.5 g q6h

Aminoglycosides

Gentamicin OR tobramycin 7 mg/kg/day
 Amikacin 20 mg/kg/day

Anti-Staphylococcal Agents (MRSA)

Vancomycin 15 mg/kg q12h, aiming for a trough of 15-20 mg/L
 Linezolid 600 mg q12h

Quinolones

Ciprofloxacin 400 mg q8h
 Levofloxacin 750 mg once daily

Colistin (Polymyxin E)

9 million units/day in three divided doses

MRSA, methicillin-resistant *Staphylococcus aureus*.

levels of biomarkers), then it may be possible to reduce the duration of therapy to as little as 7 to 8 days, although this may not be possible if the etiologic pathogen is *P. aeruginosa* or MRSA.¹⁸¹ One large study in ICU patients has shown that it is possible to reduce the duration of therapy for pneumonia, including nosocomial pneumonia, by following serial measurements of PCT. In this prospective, randomized, controlled trial, 295 patients with HAP were randomized to have therapy duration defined by clinical evaluation or a PCT algorithm, and with PCT guidance the duration of therapy was reduced by 2.3 days.¹⁰

DE-ESCALATION OF TREATMENT

Many patients with nosocomial pneumonia will get an initial empiric therapy that is broad spectrum, and thus it is important to consider de-escalation of the initial regimen as serial clinical and microbiologic data become available.¹²¹ If the patient has received a broad-spectrum regimen and the cultures do not show MDR organisms, then the patient can finish therapy with any of 7 monotherapy regimens that have been documented to be effective for severe VAP, in the absence of MDR organisms: ciprofloxacin, doripenem, imipenem, meropenem, piperacillin/tazobactam, cefepime, and high-dose levofloxacin. If *P. aeruginosa* is present, combination therapy with a β-lactam and aminoglycoside should continue for no more than 5 days, after which the patient can be switched to monotherapy with an agent to which the

organism is sensitive.² When de-escalation has been used, meaning either the switch to a more narrow-spectrum regimen, the use of fewer drugs, or both, mortality rate in VAP has been reduced, compared to when patients do not have de-escalation.^{62,63,121} There are many unrealized opportunities for using this approach, including patients with *P. aeruginosa* infection and sensitive pathogens, and in those with a good clinical response and negative respiratory tract cultures.¹²¹ Studies of de-escalation have found that the frequency of this practice varies from 22% to 74% of nosocomial pneumonia patients.⁶⁴ Factors associated with a higher rate of de-escalation are use of a protocol for when to narrow antibiotic therapy, use of initially appropriate therapy, the finding of a positive (rather than negative) respiratory tract culture, the use of an empiric broad-spectrum and multidrug regimen, and a low incidence of MDR pathogens in the ICU. The diagnostic method for pneumonia is not consistently related to the rate of de-escalation.

LOCALIZED TREATMENT

For selected patients who are infected with highly resistant organisms, and not responding to systemic antibiotics, it may be valuable to add aerosolized antibiotics (such as gentamicin, tobramycin, colistin, and ceftazidime). Aerosolized administration of antibiotics offers the advantage of achieving high concentrations of antibiotics at the site of infection, and as a result, it may be possible to overcome the problems of poor lung penetration of certain agents (aminoglycosides) and in addition, to provide the high levels of antibiotics that are needed to kill certain resistant organisms. Locally administered antibiotics are rarely absorbed, and systemic toxicity is minimized. In spite of these theoretical advantages, many efficacy questions remain to be answered by clinical trials. Aerosolized antibiotics are not usually recommended for routine treatment of pneumonia but may have a role as adjunctive therapy in patients with MDR organisms not responding to systemic therapy.¹⁸² However, new data suggest that the use of adjunctive aerosolized amikacin, delivered with a special small-particle nebulizer, in patients with a high frequency of MDR gram-negative organisms causing VAP, may lead to an earlier clinical response, resulting in a shorter duration of systemic antibiotic therapy and a lower need to escalate antibiotic therapy.¹⁸³

EVALUATION OF NONRESPONDING PATIENTS

Because pneumonia is a clinical syndrome, not all patients with this diagnosis actually have lung infection, or some may be infected with an unusual or unsuspected pathogen. In addition, some patients can develop complications of the illness or its therapy, and all of these situations may lead to an apparent nonresponse to therapy.

With effective therapy, most patients with CAP become afebrile by day 3 to 5, and most have a clinical response by day 3. Similarly, even with VAP, most patients have some improvement, particularly in oxygenation, by day 3.^{2,42} Nonresponding patients with either CAP or VAP should be evaluated for alternative diagnoses (inflammatory lung

Figure 42.6 A representative computed tomography image of the chest from a 67-year-old woman with a history of chronic obstructive pulmonary disease and bronchiectasis, admitted with right lower lobe pneumonia and empyema complicated with a bronchopleural fistula (**bold arrow**). The pleural fluid grew *Streptococcus pneumoniae* and she was treated with video-assisted thoracoscopy and decortication.

disease, atelectasis, heart failure, malignancy, pulmonary hemorrhage, pulmonary embolus, a nonpneumonic infection); a resistant or unusual pathogen (including tuberculosis and fungal infection); a pneumonia complication (empyema, lung abscess, drug fever, antibiotic-induced colitis, bronchopleural fistula) (**Fig. 42.6**); or a secondary site of infection (central-line infection, intra-abdominal infection). The evaluation of a nonresponding patient should be individualized but may include CT scanning of the chest, pulmonary angiography, bronchoscopy, and occasionally open lung biopsy.

PREVENTION

COMMUNITY-ACQUIRED PNEUMONIA

Prevention through vaccination and smoking cessation assumes importance for all groups of patients, but especially for the elderly patient and those with comorbid conditions (COPD, cardiovascular disease, diabetes, cigarette smokers, alcoholism), who are at risk for both a higher frequency of infection and a more severe course of illness. Appropriate patients should be vaccinated with both pneumococcal and influenza vaccines. Even for the patient who is recovering from CAP, immunization while in the hospital is appropriate to prevent future episodes of infection, and the evaluation of all patients for vaccination need and the provision of information about smoking cessation are now performance standards used to evaluate the hospital care of CAP patients.

PNEUMOCOCCAL VACCINATION

All high-risk patients and patients older than 65 years should be vaccinated with the 23-valent polysaccharide vaccine. It should be considered in all patients with chronic illnesses such as congestive heart failure, COPD, diabetes, asthma, chronic liver disease, functional or anatomic asplenia, and alcoholism. It is also provided to cigarette smokers, and immunocompromised adults, although the efficacy is somewhat reduced in the latter group. Immunocompromised vaccine candidates include those with HIV infection, malignancy, immune-suppressing therapy (including corticosteroids), and chronic renal failure. In those who were initially vaccinated before the age of 65 years, revaccination is provided once after 5 years. In immunocompromised patients, revaccination is given 5 years after initial vaccination. If there is uncertainty about whether the patient has recently been vaccinated, it is probably best to give a pneumococcal vaccination, because repeat administration, even more often than recommended, is not generally associated with an adverse reaction.¹⁸⁴ In a study of 62,918 adults with CAP hospitalized across 109 centers in the United States, prior vaccination against pneumococcus showed improved survival, decreased chance of respiratory failure or other complications, and decreased length of stay compared with patients who did not receive vaccination.¹⁸⁵

Hospital-based immunization is recommended, and one study found that among 1633 patients with pneumonia treated in the hospital, 62% had been hospitalized in the preceding 4 years.¹⁸⁶ In addition, 80% of these patients had a high-risk condition that would have qualified them to receive pneumococcal vaccine. Based on these observations, it seems likely that many cases of CAP could be prevented if pneumococcal vaccine was given to all hospitalized patients who qualify for the vaccine, regardless of why they are hospitalized.

INFLUENZA VACCINATION

Yearly influenza vaccine should be administered to all high-risk patients (adults 65 years of age and older, pregnant women, those with chronic comorbid medical conditions, and American Indians and Alaskan Natives) and persons who can transmit the infection to high-risk patients, such as health care workers and household members of high-risk patients.

NOSOCOMIAL PNEUMONIA

Although no single method is able to prevent nosocomial pneumonia reliably, multiple small interventions may have benefit, especially those focused on modifiable risk factors for infection. Recently, these interventions have been combined into “ventilator bundles,” which have been demonstrated to reduce the incidence of VAP, if applied carefully.^{187,188} Most of these bundles include multiple interventions, so it is difficult to know which individual manipulations are most valuable. Successful bundles have included interventions such as elevation of the head of the bed to 30 degrees (to avoid the risk of aspiration present with the supine position), daily interruption of sedation to attempt weaning, peptic ulcer disease prophylaxis, endotracheal tube suctioning (possibly with a closed suction system),

hand washing, careful oral care (including oral chlorhexidine), and tight control of blood glucose.⁴⁰ In spite of the success of this approach, one recent randomized study has demonstrated a lack of benefit and feasibility of routine elevation of the head of the bed.¹⁸⁹ The efficacy of this approach has led to a movement to aim for “zero VAP” in all ICUs, but it remains uncertain if this goal is really achievable, and if hospitals that consistently report this result have simply changed the diagnostic criteria for VAP, because in many instances, the incidence of VAP has been reduced, without a reduction in associated outcomes such as mortality rate and ICU length of stay.

Other widely used measures in mechanically ventilated patients are avoidance of large inocula of bacteria into the lung (careful handling of ventilator circuit tubing), mobilization of respiratory secretions (frequent suctioning, use of rotational bed therapy in selected individuals), nutritional support (enteral preferred over parenteral), placing of feeding tubes into the small bowel (to avoid aspiration, which is more likely with stomach tubes), and avoidance of large gastric residuals when giving enteral feeding. In addition, any tube inserted into the stomach or trachea should be inserted through the mouth and not the nose, whenever possible, to avoid obstructing the nasal sinuses, and to prevent nosocomial sinusitis, which can lead to nosocomial pneumonia.⁴⁰ A specially adapted endotracheal tube that allows for continuous aspiration of subglottic secretions may interrupt the oropharyngeal to tracheal transfer of bacteria and reduce the incidence of pneumonia.¹⁹⁰ In addition, modifications of the endotracheal tube have been developed, including silver coating of the tube and a focus on maintaining endotracheal tube cuff pressure to avoid leakage of tracheal secretions to the lung, and both approaches have had some success. In addition, new devices to remove biofilm from the surface of the endotracheal tube are in development, but their clinical benefit is not yet defined. Because endotracheal intubation is a risk for pneumonia, noninvasive positive-pressure ventilation should be used whenever possible, and this approach is associated with a lower pneumonia risk than traditional mechanical ventilation. Early tracheostomy has been considered a potentially effective means of VAP prevention, but a large randomized trial did not confirm such a benefit.¹⁹¹ There is no specific role for prophylactic systemic or topical antibiotics, but some data suggest that patients with coma due to stroke or head trauma and those who may have aspirated during an emergent intubation may benefit from a 24-hour course of systemic antibiotics.¹⁹² The use of selective digestive decontamination (SDD), which involves the use of prophylactic systemic and topical (mouth and intestinal tract) antimicrobials, has been a controversial strategy for VAP prevention for many years. Although one large trial has recently reported benefit, there are many concerns with this approach, including the development of antibiotic resistance, and the possibility that the use of oral chlorhexidine and ventilator bundles may be just as effective as the entire SDD regimen.^{193,194}

KEY POINTS

- Patients with severe CAP admitted to the ICU, as well as patients with VAP, continue to have a high mortality rate, despite initiation of multiple novel therapeutic and preventive strategies in the ICU.
- Delay in ICU admission in patients with severe CAP is associated with increased mortality risk.
- Scoring systems such as the ATS/IDSA 2007 definition for severe pneumonia and PIRO (predisposition, insult, response, and organ dysfunction) scores are useful for assessing the severity of illness in CAP patients.
- The use of biomarkers, such as procalcitonin, to diagnose the severity and guide the use and duration of antimicrobial therapy in patients with severe CAP and VAP is being adopted increasingly in various ICUs.
- *S. pneumoniae* is the most common pathogen causing severe CAP, and enteric gram-negative bacteria and *S. aureus* are the most common causes of nosocomial pneumonia.
- HCAP is much more heterogeneous than previously thought and not all patients require empiric broad-spectrum antibiotic therapy directed at multidrug-resistant pathogens.
- The most important risk factor for death in patients with VAP is inappropriate empiric antibiotic therapy; other mortality risk factors include respiratory failure, coma on admission, bilateral radiographic abnormalities, and infection with resistant organisms.
- Initiation of appropriate and early antibiotic therapy in patients with severe pneumonia is associated with increased survival.
- In choosing an antibiotic for a patient with severe pneumonia, history of recent antibiotic use and local antibiogram is crucial, and care should be taken to avoid using the same antibiotics prescribed in the recent past (3 months for a patient with CAP, and any agent prescribed in the last 2 weeks for a patient with VAP).
- Empiric broad-spectrum antibiotics are required for patients with severe pneumonia. However, patients should be reevaluated after 72 hours and efforts should be made to narrow the spectrum of therapy and the number of drugs based on microbiologic data and clinical response.
- Nonresponders should be evaluated for treatment failure or complications from infection.
- Use of hospital-based immunization practices has helped reduce the incidence of CAP, and use of “ventilator bundles” in the ICU is associated with a significant reduction in the incidence of VAP.

Weaning by Protocol Versus Usual Care

EXTUBATION

CONCLUSION

Mechanical ventilation is often lifesaving, but it is associated with numerous complications.^{1,2} Accordingly, it is imperative to disconnect patients from the ventilator at the earliest feasible time. Deciding the right time to initiate this disconnection process, usually referred to as *weaning*, is one of the greatest challenges in critical care medicine.³ If a physician is too conservative and postpones the initiation of weaning, the patient is placed at an increased risk of life-threatening, ventilator-associated complications. Conversely, if weaning is begun prematurely, the patient may suffer cardiopulmonary or psychological decompensation of sufficient severity to set back a patient's clinical course.⁴

This chapter reviews the pathophysiology of weaning failure, weaning-predictor testing, different weaning techniques, and extubation.

PATHOPHYSIOLOGY OF WEANING FAILURE

After patients have been disconnected from the ventilator, up to 25% experience respiratory distress severe enough to necessitate the reinstitution of mechanical ventilation.^{5,6} The pathophysiologic mechanisms of weaning failure can be divided into those occurring at the level of the respiratory control system, mechanics of the lung and chest wall, the respiratory muscles, the cardiovascular system, and gas-exchange properties of the lung.⁷

CONTROL OF BREATHING

Many weaning-failure patients develop hypercapnia. Accordingly, it had been thought that these patients experience an acute decrease in minute ventilation consequent to a decrease in respiratory center output.³ Measurements of respiratory motor output, using mean inspiratory flow or airway occlusion pressure ($P_{0.1}$), have consistently revealed an increase, not a decrease, in respiratory drive in weaning-failure patients.^{4,8,9}

Weaning-failure patients, however, exhibit marked abnormalities in respiratory timing, specifically marked shortening of inspiratory time (T_I), which is coupled with shortening of expiratory time (T_E). The decrease in both T_I and T_E means that respiratory frequency (f) is markedly elevated. The shortening of T_I combined with a normal mean inspiratory flow (V_T/T_I) results in a marked decrease of tidal volume (V_T).⁸ This combination (elevated f and decreased V_T) is referred to as rapid shallow breathing—now recognized as the physiologic hallmark of weaning failure (Fig. 43.1).³

RESPIRATORY MECHANICS

The most detailed study of respiratory mechanics during weaning trials was carried out by Jubran and Tobin.^{10,11} Immediately before commencement of a trial of spontaneous breathing, patients who went on to tolerate or

Figure 43.1 The mean respiratory cycle during spontaneous breathing in 7 weaning-failure patients and 10 weaning-success patients. The early termination of inspiratory time in the weaning-failure patients leads to a decrease in tidal volume (V_T). The decrease in inspiratory time, coupled with a decrease in expiratory time, results in a faster respiratory frequency. Bars represent 1 SE. (Redrawn from Tobin MJ, Perez W, Guenther SM, et al: The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis* 1986;134:1111-1118.)

fail the trial showed little or no difference in detailed measurements of passive respiratory mechanics.¹¹ Resistance, elastance, and intrinsic positive end-expiratory pressure (PEEPi) were equivalent in the two groups.

Over the course of the trial, all of these variables became more abnormal in the weaning-failure patients than in the weaning-success patients (Fig. 43.2).¹⁰ Respiratory resistance increased progressively, reaching about seven times the normal value at the end of the trial. Pulmonary elastance increased, reaching five times the normal value. Intrinsic PEEP more than doubled over the course of the trial. A similar pattern has been observed by other investigators.¹² The observation that respiratory mechanics were equivalent in weaning-success and weaning-failure patients immediately before a weaning trial but deteriorated immediately in the weaning-failure patients as soon as they began to breathe spontaneously indicates that some mechanism associated with the act of spontaneous breathing causes the worsening of respiratory mechanics that leads to weaning failure.

PATIENT EFFORT

To compensate for the marked worsening of respiratory mechanics, patients need to make a greater inspiratory effort. It had been thought that weaning-failure patients make weaker inspiratory efforts than do weaning-success patients.⁷ On the contrary, direct measurements of work of breathing and pressure-time product^{13,14} show that weaning-failure patients consistently make a greater inspiratory effort than do weaning-success patients (Fig. 43.3).^{10,15}

Figure 43.2 Inspiratory resistance of the lung ($R_{insp,L}$), dynamic lung elastance ($E_{dyn,L}$), and intrinsic positive end-expiratory pressure (PEEPi) in 17 weaning-failure patients and 14 weaning-success patients. Data displayed were obtained during the second and last minutes of a T-tube trial, and at one third and two thirds of the trial duration. Between the onset and end of the trial, the failure group developed increases in $R_{insp,L}$ ($P < 0.009$), $E_{dyn,L}$ ($P < 0.0001$), and PEEPi ($P < 0.0001$) and the success group developed increases in $E_{dyn,L}$ ($P < 0.006$) and PEEPi ($P < 0.02$). Over the course of the trial, the failure group had higher values of $R_{insp,L}$ ($P < 0.003$), $E_{dyn,L}$ ($P < 0.006$), and PEEPi ($P < 0.009$) than the success group. (Redrawn from Jubran A, Tobin MJ: Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1997;155:906-915.)

RESPIRATORY MUSCLES

Numerous research groups have shown that maximal inspiratory pressure (P_{imax}), a measure of respiratory muscle strength, does not discriminate between weaning-success and weaning-failure patients.⁷ These findings led to the belief that respiratory muscle weakness is not an important determinant of weaning outcome. P_{imax} , however, can misrepresent respiratory muscle strength because the values are heavily influenced by patient motivation and cooperation.¹³ A more objective measure of diaphragmatic strength is obtained by stimulation of the phrenic nerves and recording the resulting transdiaphragmatic pressure (Pdi). Weaning-failure patients have twitch Pdi values below 10 cm H₂O, whereas values of 35 to 39 cm H₂O are observed in healthy subjects.¹⁶ These data suggest that weaning-failure patients may have considerable muscle weakness.

Stimulation of the phrenic nerves and recording of the resulting Pdi also provides the most direct measure of diaphragmatic fatigue.¹³ Laghi and coworkers¹⁷ employed this technique in 11 weaning-failure and 8 weaning-success patients before and after a T-tube trial. No patient in either group exhibited a fall in twitch pressure. This result was surprising. Related analyses disclosed why. Failure patients became progressively distressed during the trial, leading

Figure 43.3 Ensemble average plots of flow and esophageal pressure (Pes) at the start and end of a T-tube trial in 17 weaning-failure patients and 14 weaning-success patients. At the start of the trial, the inspiratory excursion in Pes was greater in the failure patients, and it increased further by the end of the trial. To generate these plots, flow and Pes tracings were divided into 25 equal time intervals over a single respiratory cycle for each of the five breaths for each patient in the two groups. For a given patient, the five breaths from the start of the trial were then superimposed and aligned with respect to time, and the average at each time point was calculated. The group mean tracings were then generated by ensemble averaging of the individual mean from each patient. The same procedure was performed for breaths at the end of the trial. (Redrawn from Jubran A, Tobin MJ: Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1997;155:906-915.)

clinicians to reinstate ventilator support before patients had breathed long enough to develop fatigue (Fig. 43.4).^{17,18} In other words, monitoring clinical signs of distress provides sufficient warning to avoid respiratory muscle fatigue.

CARDIOVASCULAR PERFORMANCE

During a weaning trial, patients can experience substantial increases in right and left ventricular afterload.^{19,20} These afterload increases most likely result from associated increases in negative swings of intrathoracic pressure. At the completion of a weaning trial, the level of oxygen consumption is equivalent in weaning-success and weaning-failure patients. How the cardiovascular system meets the oxygen demand differs in the two groups of patients. In weaning-success patients, oxygen demand is met through an increase in oxygen delivery, mediated by the expected increase in cardiac output on discontinuation of positive-pressure ventilation.²⁰ In weaning-failure patients, oxygen demand is met through an increase in oxygen extraction; these patients have a relative decrease in oxygen delivery.²⁰ The greater oxygen extraction causes a substantial decrease in mixed venous oxygen saturation, contributing to the arterial hypoxemia that occurs in some patients.²⁰

GAS EXCHANGE

Studies employing the multiple inert-gas technique have revealed that the ventilation-perfusion maldistribution and acute hypercapnia observed in weaning-failure patients is produced primarily by shallow breathing (low V_T).⁷ About half of weaning-failure patients experience an increase in $Paco_2$ of 10 mm Hg or more over the course of a spontaneous breathing trial.¹⁰ The hypercapnia is not usually a

consequence of a decrease in minute ventilation. Instead, it results from rapid, shallow breathing, which causes an increase in dead space ventilation. In a small proportion of weaning-failure patients, primary depression of respiratory motor output may be responsible for the hypercapnia.¹⁰

WEANING-PREDICTOR TESTING

In randomized controlled trials (RCTs) of different weaning techniques, most patients who had received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured.^{5,6} Many of these patients probably would have tolerated extubation a day or so earlier. As such, one of the main sources of weaning delay is the failure of the physician to think that the patient just might come off the ventilator. Psychological research suggests that much of this delay in ventilator weaning results from clinicians being overconfident in their intuition that a patient is not ready for a weaning trial.⁴ Another source of error is the failure of clinicians to pay close attention to pretest probability—they fail to recognize the importance of bayesian principles in clinical decision making. When taking care of a ventilator-supported patient, physicians should be mindful of these cognitive processes and employ compensatory tactics, specifically the use of screening tests, to spot a patient's readiness for weaning. By alerting an unsuspecting physician to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision making.⁴

Figure 43.4 Interrelationship between the duration of a spontaneous breathing trial, tension-time index of the diaphragm, and predicted time to task failure in nine patients who failed a trial of weaning from mechanical ventilation. The patients breathed spontaneously for an average of 44 minutes before a physician terminated the trial. At the start of the trial, the tension-time index was 0.17, and the formula of Bellemare and Grassino¹⁸ predicted that patients could sustain spontaneous breathing for another 59 minutes before developing task failure. As the trial progressed, the tension-time index increased and the predicted time to development of task failure decreased. At the end of the trial, the tension-time index reached 0.26. That patients were predicted to sustain spontaneous breathing for another 13 minutes before developing task failure clarifies why patients did not develop a decrease in diaphragmatic twitch pressure. In other words, physicians interrupted the trial on the basis of clinical manifestations of respiratory distress, before patients had sufficient time to develop contractile fatigue. (Redrawn from Laghi F, Tobin MJ: Disorders of the respiratory muscles. *Am J Respir Crit Care Med* 2003;168:10-48.)

PITFALLS IN USE OF WEANING-PREDICTOR TESTS

Physicians commonly view diagnostic testing in monolithic terms: a test is a test is a test. In reality, diagnostic testing has to satisfy two very different tasks: one is screening, the other is confirmation.²¹ The characteristics of these test types differ, and a single diagnostic test rarely fulfills both functions.²¹

The fundamental job of a weaning-predictor test is screening.⁴ Because the goal is to not miss anybody with the condition under consideration, a good screening test has a low rate of false-negative results; to achieve this goal, a higher false-positive rate is acceptable. Thus an ideal screening test has a high sensitivity.^{4,21}

Weaning involves the use of three diagnostic tests in sequence: measurement of predictors, a weaning trial, and a trial of extubation.⁴ The sequential nature of the testing gives rise to particular problems in studies undertaken to investigate the reliability of a predictor test. One is spectrum bias. This occurs when a new study population contains fewer (or more) sick patients than the population in which a diagnostic test was originally developed.^{21,22} A second is

test-referral bias. This occurs when the results of a test under evaluation are used to select patients for a reference-standard test, such as use of a weaning-predictor test to select patients for a reference-standard test (passing a weaning trial that leads to extubation).^{21,22}

A third factor that affects studies of the reliability of a predictor test is base-rate fallacy.^{22,23} Consider a diagnostic test for a disease that has a false-positive rate of 5% and false-negative rate of 0%, and the incidence of the disorder (under consideration) is 1 per 1000 persons. A randomly selected person undergoes diagnostic testing. The result comes back positive. What is the chance this person has the disease? More than 80% of physicians answer 95%. The correct answer is 1.96%.²³ Physicians who answer 95% are failing to take into account the pretest probability of the disorder. Thus they fall into the trap of base-rate fallacy.

Pretest probability is a physician's estimate of the likelihood of a particular condition (weaning outcome) before a diagnostic test is undertaken.⁴ Post-test probability (typically expressed as positive or negative predictive value) is the new likelihood after the test results are obtained. A good diagnostic test achieves a marked increase (or decrease) in the post-test probability (over pretest probability). For every test in every medical subspecialty, the magnitude of change between pretest probability and post-test probability is determined by Bayes's theorem.²² Three factors (alone) determine the magnitude of the pretest to post-test change: sensitivity, specificity, and pretest probability. Sensitivity and specificity are commonly assumed to remain constant for a test. In truth, test-referral bias, a common occurrence in studies of weaning tests, leads to major changes in sensitivity and specificity.²¹ Likewise, major changes in pretest probability arise as a consequence of spectrum bias.²¹ All of these factors need to be carefully considered when reading a study that evaluates the reliability of a weaning-predictor test.

RESPIRATORY FREQUENCY/TIDAL VOLUME RATIO

The ratio of respiratory frequency to tidal volume (f/V_T) is measured during 1 minute of spontaneous breathing (Fig. 43.5).²⁴ Measurements of f/V_T in the presence of pressure support or continuous positive airway pressure (CPAP) will result in inaccurate predictions of weaning outcome.⁴ The higher the f/V_T ratio, the more severe the rapid, shallow breathing and the greater the likelihood of unsuccessful weaning. An f/V_T ratio of 100 best discriminates between successful and unsuccessful attempts at weaning.²⁴

The initial evaluation of f/V_T was reported in 1991.²⁴ Since then, this test has been evaluated in more than 25 studies. Reported sensitivity ranges from 0.35 to 1.²² Specificity ranges from 0 to 0.89.²² At first glance, this wide scatter suggests that f/V_T is an unreliable predictor of weaning outcome. This was also the viewpoint of an Evidence-Based Medicine Task Force that undertook a meta-analysis of the studies.^{25,26} The Task Force, however, failed to take into account test-referral bias and spectrum bias.⁴ In consequence, the Task Force committed at least 15 major errors—any one of which was sufficient to scupper their conclusions.^{27,28} In contrast, when data from the studies (included in the meta-analysis) were compared against the test characteristics in the original 1991 report, taking into

Figure 43.5 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The arrow indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. (Redrawn from Tobin MJ, Perez W, Guenther SM, et al: The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis* 1986;134:1111-1118.)

account bayesian pretest probability, the weighted Pearson correlation coefficient was 0.86 ($P < 0.0001$) for positive predictive value and 0.82 ($P < 0.0001$) for negative predictive value (Figs. 43.6 and 43.7).²²

The primary job of a weaning-predictor test is screening, which requires a high sensitivity.^{4,21} The average sensitivity in all of the studies on f/V_T was 0.89, and 85% of the studies reveal sensitivities higher than 0.90.²² This sensitivity compares well with commonly used diagnostic tests.⁴

The whole purpose of diagnostic screening is to perform a simple test at a time when a physician's pretest probability is low (less than 50%).⁴ A screening test should be cheap, easy to perform, pose minimal risk to patients, and provide a quick answer. A spontaneous breathing trial that involves 30 to 120 minutes of monitored performance is the antithesis of a screening test. Yet, the Evidence-Based Medicine Task Force recommends that clinicians should start weaning with a spontaneous breathing trial (a confirmatory test), and use the initial few minutes of the trial as a screening test.²⁵ This is analogous to saying that when you suspect diabetes, start with a glucose tolerance test and then, as the test gets under way, ask the patient for a urine sample in order to do a dipstick.²⁹

WEANING TRIALS

When a screening test is positive, the clinician proceeds to a confirmatory test.²¹ The goal of a positive result on a

Figure 43.6 Positive predictive value (post-test probability of successful outcome) for f/V_T plotted against pretest probability of successful outcome. The curve is based on the sensitivity and specificity originally reported by Yang and Tobin²⁴ and Bayes's formula for 0.01-unit increments in pretest probability between 0.00 and 1.00.²² The lines represent the upper and lower 95% confidence intervals for the predicted relationship of the positive predictive values against pretest probability. The observed positive predictive value in a study is plotted against the pretest probability of weaning success (prevalence of successful outcome). (Redrawn from Tobin MJ, Jubran A: Variable performance of weaning-predictor tests: Role of Bayes' theorem and spectrum and test-referral bias. *Intensive Care Med* 2006;32:2002-2012.)

Figure 43.7 Negative predictive value (post-test probability of unsuccessful outcome) for f/V_T. The curve, its 95% confidence intervals, and placement of a study on the plot are described in the legend of Figure 43.6. The observed negative predictive value in a study is plotted against the pretest probability of weaning success (prevalence of successful outcome). (Redrawn from Tobin MJ, Jubran A: Variable performance of weaning-predictor tests: Role of Bayes' theorem and spectrum and test-referral bias. *Intensive Care Med* 2006;32:2002-2012.)

confirmatory test is to rule in a condition¹⁹. The likelihood of a patient tolerating a trial of extubation is high. An ideal confirmatory test has a low rate of false-positive results (i.e., a high specificity).²¹ Unfortunately, the specificity of a spontaneous breathing trial is not known. Indeed, its specificity will never be known because its determination would require an unethical experiment: extubating all patients who fail a weaning trial and counting how many require reintubation.⁴

MULTIPLE T-TUBE TRIALS

Of the four methods available for conducting a weaning trial, the use of repeated T-tube trials, several times a day, is the oldest method.³ The patient receives an enriched supply of oxygen through a T-tube circuit. Initially 5 to 10 minutes in duration, T-tube trials are extended and repeated several times a day until the patient can sustain spontaneous ventilation for several hours. This approach has become unpopular because it requires considerable time on the part of intensive care staff.

INTERMITTENT MANDATORY VENTILATION

For many years, intermittent mandatory ventilation (IMV) was the most popular method of weaning.³ With IMV, the mandatory rate from the ventilator is reduced in steps of 1 to 3 breaths per minute, and an arterial blood gas value is obtained about 30 minutes after each rate change.³⁰ Unfortunately, titrating the number of breaths from the ventilator in accordance with the results of arterial blood gases can produce a false sense of security. As few as two to three positive-pressure breaths per minute can achieve acceptable blood gas values, but these values provide no information regarding the patient's work of breathing (which may be excessive).⁴ At IMV rates of 14 breaths per minute or fewer, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue.^{31,32} Moreover, this occurs not only with the intervening spontaneous breaths but also with ventilator-assisted breaths. Consequently, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery.⁷

PRESSURE SUPPORT

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3 to 6 cm H₂O) and titrated on the basis of the patient's respiratory frequency.³³ When the patient tolerates a minimal level of pressure support, he or she is extubated. What exactly constitutes a "minimal level of pressure support" has never been defined.³⁴

ONCE-DAILY T-TUBE TRIALS

The fourth method of weaning is to perform a single daily T-tube trial, lasting for 30 to 120 minutes. If this trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 hours of respiratory muscle rest with full ventilator support before another trial is performed.⁴

COMPARISON OF WEANING METHODS

Until the early 1990s, it was widely believed that all weaning methods were equally effective, and the physician's judgment was regarded as the critical determinant.³ The results of RCTs have revealed that the period of weaning is as much as three times as long with IMV as with trials of spontaneous breathing.^{5,6} In a study involving patients with respiratory difficulties on weaning, trials of spontaneous breathing halved the weaning time as compared with pressure support⁶; in another study, the weaning time was similar with the two methods.⁵ Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day but much simpler.⁶ In patients not expecting to pose any particular difficulty with weaning, a half-hour trial of spontaneous breathing is as effective as a 2-hour trial.³⁵

WEANING BY PROTOCOL VERSUS USUAL CARE

Six groups of investigators have undertaken RCTs comparing the use of protocols versus usual care in the management of weaning. Three groups—Namen and colleagues,³⁶ Randolph and associates,³⁷ and Krishnan and coworkers³⁸—found that protocolized weaning was without benefit. Data from the other three studies are sometimes viewed as supportive of the superiority of protocolized weaning. The studies by Kollef and colleagues³⁹ and by Ely and associates,⁴⁰ however, contain internal-validity problems of such magnitude that the data cannot be accepted as valid evidence on which to base a claim that protocols per se expedite weaning. The third study, by Marelich and coworkers,⁴¹ revealed no benefit in one of the two ICUs in the study. In summary, only half of one study out of six studies revealed valid support for protocolized weaning, with the remainder providing no evidence of benefit.

Tanios and colleagues⁴² undertook an RCT to determine whether the inclusion of f/V_T in a weaning protocol influenced weaning time. In the f/V_T-protocol group, patients could proceed to a weaning trial (CPAP and pressure support) if—and only if—they had an f/V_T of less than 106. In the second study arm, clinicians did not follow the protocolized approach to weaning. The duration of weaning was longer in the f/V_T-protocol group than in the nonprotocol group.

The study has two major problems. First, the investigators assume that physicians managing patients in the control group did not calculate f/V_T. Physicians, however, are highly aware that respiratory frequency and tidal volume are key variables in deciding whether a patient will tolerate weaning and extubation.³ Once this knowledge has crept into a physician's brain, it cannot be surgically extirpated at the point of commencing an RCT. To ensure that physicians did not employ breathing pattern in the decision making, Tanios and colleagues⁴² would have had to have taken steps to hide or occlude the display of frequency and tidal volume on the bedside monitor and ventilator screen.

Second, f/V_T was one component in a weaning protocol. It is important to make a distinction between the use of a protocol in conducting a research study and its use in everyday clinical practice. In the research protocol of Tanios and colleagues,⁴² patients who had an f/V_T of 105 or less

progressed to a weaning trial, whereas patients with an f/V_T of 106 or higher were returned to the ventilator. When conducting research, this is exactly how a protocol must be specified and followed. No flexibility is permitted. A competent clinician, however, would think it daft to slavishly comply with a protocol that decided an entire day of ventilator management on a one-unit difference in a single measurement of f/V_T .⁴³ Rather, intelligent physicians customize knowledge to the particulars of each patient and are expected to outperform the inflexible application of a protocol—as has been shown in numerous studies of weaning protocols.

EXTUBATION

Decisions about weaning and decisions about extubation are commonly combined.⁴⁴ When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician must also judge whether or not the patient will be able to maintain a patent upper airway after extubation.

Of patients who are expected to tolerate extubation without difficulty, approximately 10% to 20% fail and require reintubation.^{5,6} The mortality rate among patients who require reintubation is more than six times as high as the mortality rate among patients who can tolerate extubation.³⁵ The reason for the higher mortality rate is unknown. It might be related to the development of new problems after extubation or to complications associated with reinsertion of a new tube. A more likely explanation is that the need for reintubation reflects greater severity of the underlying illness.⁴²

Many physicians find it convenient to extubate a patient once he or she can breathe comfortably on a pressure support of about 7 cm H₂O and PEEP 5 cm H₂O based on the belief that such “minimal ventilator settings” are simply overcoming the resistance engendered by an endotracheal tube.⁴⁵ This claim ignores the inflammation and edema that develop in the upper airways after an endotracheal tube has been in place for a day or more. On removal of the tube, the mucosal swelling produces an increase in upper airway resistance. Straus and associates⁴⁶ demonstrated experimentally that the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against an endotracheal tube before extubation. Thus, applying any level of pressure support causes physicians to underestimate the respiratory resistance a patient will encounter after extubation. The addition of a small amount of pressure support produces surprisingly large reductions in inspiratory work in ventilated patients: 5 cm H₂O decreases inspiratory work by 31% to 38% and 10 cm H₂O decreases work by 46% to 60%.^{34,47} Independently, the addition of 5 cm H₂O of PEEP can decrease the work of breathing by as much as 40% in ventilated patients.⁴ In the case of a patient who might experience cardiorespiratory difficulties after extubation, it is incumbent on a physician to ensure that the patient is able to breathe comfortably for about 30 minutes in the

complete absence of pressure support or PEEP before removal of the endotracheal tube.⁴⁵

CONCLUSION

In conclusion, to minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. Because each step constitutes a diagnostic test, clinicians must be mindful of the scientific principles of diagnostic testing when interpreting the information generated by each step. The critical step is for the physician to contemplate the possibility that a patient *just might* be able to tolerate weaning. Such diagnostic triggering is assisted through the use of a screening test, which is the rationale for measurement of weaning-predictor tests. Importantly, one should not postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial. Many complex facets of pulmonary pathophysiology impinge on weaning management. Thus, weaning requires individualized care at a high level of sophistication.

KEY POINTS

- Most patients who fail a trial of weaning from mechanical ventilation do so because of a markedly increased respiratory load, which, in turn, is secondary to severe worsening of respiratory mechanics over the course of the weaning trial.
- Less common reasons for weaning failure include weakened respiratory muscles or impaired cardiovascular performance; primary abnormalities of the respiratory centers or intrapulmonary shunt are uncommon mechanisms of weaning failure.
- Several studies suggest that most patients weaned successfully could have tolerated the weaning attempts had they been initiated a day or more earlier. Such data emphasize the need for the early use of screening tests.
- The primary goal of a screening test is to not miss anybody with the condition under consideration; thus, the test should have a high sensitivity. The ratio of respiratory frequency to tidal volume (f/V_T) has been evaluated in more than 25 studies; its average sensitivity is 0.89.
- Weaning involves the undertaking of three diagnostic tests in sequence. The sequential nature of the testing predisposes to the occurrence of test-referral bias and spectrum bias.
- Of the techniques used for a weaning trial, IMV has been repeatedly shown to be inferior to the use of T-tube trials or pressure support.
- Six randomized trials have evaluated the usefulness of protocols in the management of weaning. Three studies observed no benefit with the use of protocols. Two of the remaining three studies had major methodologic problems, leaving only one study supporting the use of protocols.

LONG-TERM PROGNOSIS

Pulmonary venous thromboembolism (VTE) and deep venous thrombosis (DVT) are different manifestations of the same disease. Despite adequate VTE prophylaxis in the intensive care unit (ICU) the presence of a VTE event is a constant threat to critically ill patients. Although the critical care clinician may encounter the embolization of air, fat, infected clots, amniotic fluid, tumor, and inorganic substances, by far VTE will be the most common pulmonary embolic condition encountered. Critical care clinicians will encounter life-threatening pulmonary embolism (PE) ranging from hemodynamically stable patients with varying degrees of right ventricular dysfunction (RVD) to acute massive PE, defined as hemodynamic shock from acute PE,

which represents the most serious manifestation along the spectrum of venous thromboembolic disease.¹⁻³ According to population-based studies, the annual incidence of VTE in the United States has ranged from 200,000 to a recent estimate of 900,000 cases in which approximately 300,000 people die every year from acute PE.^{4,5} More recently, in 2006, 467,000 patients were hospitalized with DVT and 247,000 patients were admitted with acute PE.⁶ VTE is associated with a significant health care costs. Based on 2004 provider payments, the economic burden of VTE costs ranges between \$5.8 billion and \$7.8 billion.⁷

The mortality rate can exceed 58% in patients with acute PE presenting with shock, and most of these deaths occur within 1 hour of presentation.^{1,2} Acute PE is the third most common cause of death among hospitalized patients, and

Additional online-only material indicated by icon.

with an aging population the number of people with VTE is expected to increase. For these reasons, the U.S. Surgeon General issued a “Call to Action” in 2008, identifying VTE as a major public health problem.⁸

The development of DVT occurs largely in the lower extremities and can result in the sequelae of PE, post-thrombotic syndrome, and chronic thrombotic pulmonary hypertension.⁹ Venous thrombosis is associated with significant morbidity and mortality rates but can be prevented in most patients.^{2,3}

In this chapter we will review the epidemiology, risk factors, diagnosis, risk assessment, and management of acute PE. In our discussion we will review VTE in special adult populations, VTE prophylaxis in the ICU, and long-term prognosis.

PREVALENCE OF VENOUS THROMBOEMBOLISM IN INTENSIVE CARE UNIT PATIENTS

ICU patients represent a heterogeneous population. In prospective screening studies for DVT, in the absence of thromboprophylaxis, the incidence of DVT in a medical-surgical ICU ranges from approximately 13% to 33%.¹⁰⁻¹² In an autopsy review of six studies of 436 critically ill patients the incidence of PE ranged from 7% to 27% (mean 13%); PE contributed or directly caused death in 0% to 12% (mean 3%) of the patients. It is important to note that in a majority of the patients there was no antemortem suspicion of fatal PE.¹³

Contemporary prevalence of VTE that are admitted to or occur in the ICU setting can be obtained from large VTE clinical trials. Approximately 10% of patients entered into the PIOPED-I (Prospective Investigation of Pulmonary Embolism Diagnosis) study for possible PE were hospitalized in a medical or surgical critical care unit.¹⁴ In the recent international, multicenter EINSTEIN PE trial,¹⁵ which randomized 4823 symptomatic PE patients to rivaroxaban or enoxaparin and a vitamin K antagonist, 600 patients (12.4%) required ICU admission. Finally, in the PROTECT trial (Prophylaxis for Thromboembolism in Critical Care Trial)¹⁶ among 3764 critically ill patients enrolled in which a majority were on mechanical ventilator support and 40% were on vasopressor therapy, dalteparin and unfractionated heparin (UFH) were the agents used for VTE prophylaxis. The primary end point was proximal DVT presence. Using compression ultrasonography (CUS), 3.5% of the patients had

proximal DVT on admission. The incidence of proximal DVT was 5.1% in the dalteparin group and 5.4% in the UFH group. The proportion of patients with pulmonary emboli was significantly lower with dalteparin (24 patients, 1.3%) than with UFH (43 patients, 2.3%).¹⁶

There is controversy over routine DVT screening in the ICU. As mentioned earlier, most ICU patients with DVT are asymptomatic and the clinical signs for DVT are nonspecific. CUS is time consuming and not cost effective. Efforts must be made to ensure adherence to current DVT prophylaxis guidelines. In ICU patients in whom these guidelines cannot not be fully implemented (intracranial, spinal, or leg injuries, or patients at increased bleeding risk) then routine CUS screening may be appropriate.¹⁷⁻²¹

RISK FACTORS

In the nineteenth century Virchow described stasis, vascular wall abnormalities, and hypercoagulability as general risk factors for the development of DVT.²²

As illustrated in Table 44.1, patients admitted to the ICU possess multiple preexisting VTE risks factors on admission to the ICU, yet in the International Cooperative Pulmonary Embolism Registry (ICOPER) 20% of the patients had idiopathic or unprovoked PE.³

The interaction between patient-related and setting-related risk factors appears to be responsible for the development of the VTE.²³⁻²⁵ Patient-related risk factors are usually acquired and are longstanding. Examples of patient-related risk factors are age, history of prior VTE, malignancy, neurologic and medical illnesses that result in immobility, cardiopulmonary disorders, collagen vascular disease, and vasculitis. In addition, patient-related factors may include genetic and acquired thrombophilia and hormone replacement therapy and oral contraceptive therapy. Setting-related risk factors are usually temporary. Examples of setting-related risk factors include hospitalizations, nursing home placement, and admission to the ICU.

Virchow has described several risk factors unique to the ICU setting that predispose patients to VTE events. In a prospective observational study of 93 medical-surgical ICU patients, the investigators identified several ICU-related factors that are associated with increased risk of VTE, including mechanical ventilation, immobility, femoral venous catheters, sedatives and paralytic drugs, and failure to prescribe VTE prophylaxis. Prolonged mobility in the ICU setting is the result of mechanical ventilation, sedative

Table 44.1 Selected Risk Factors for Venous Thromboembolism (VTE)

Genetic Risk Factors	Acquired Risk Factors	Triggering Risk Factors	ICU-Acquired Risk Factors
Antithrombin III deficiency	Age	Surgery	Sepsis
Protein S and C deficiency	Previous VTE	Pregnancy	Vasopressor use
Prothrombin gene mutation	Obesity	Estrogens	Central venous line
	Malignancy	Immobility	Platelet transfusions
	Antiphospholipid syndrome		Pharmacologic paralysis
	Collagen vascular disease		Use of recombinant factor VIIa

ICU, intensive care unit.

administration, and paralytic agents. These four factors (mechanical ventilation, immobility, sedation, and paralysis) may converge to greatly increase the risk of VTE.²⁶ Sedation and paralysis also predispose to other ICU complications including increased duration of mechanical ventilation, and critical illness polyneuropathy.^{27,28}

DEEP VEIN THROMBOSIS

It is estimated that as high as 95% of clinically significant pulmonary emboli originate from the deep veins of the lower extremity. The proximal deep veins of the leg are the most common sites of origin of clots that embolize to the pulmonary circulation. A general consensus suggests that clinically significant proximal DVTs and risk for PEs originate by proximal extension of calf DVT.^{47,48} Venous thrombi are created in the setting of low flow and low shear stress. These thrombi consist of fibrin strands, red blood cells, and platelets. The thrombi form in the valve pockets of calf veins and extend to the proximal veins.⁴⁸ After the thrombosis is formed there is raised venous capillary pressure, which increases the transcapillary filtration and the pressure rate, resulting in edema. In approximately 50% of patients, venous outflow obstruction decreases within 3 months by lysis and recanalization.⁴⁹ Patients who have early edema are most likely to have residual thrombosis. Clots that continue to propagate have a greater risk to break apart and lead to embolization. This generally occurs more frequently in the first few days after clot formation. Clots that do not continue to propagate resolve by either fibrinolysis or organization. These processes generally occur within 7 days of clot formation.^{49,50}

In general only 25% of patients with suspected DVT actually have it.⁴⁷ The detection of DVT in critically ill patients is hampered by the patient's inability to report symptoms and the unreliability of physical signs of DVT. CUS is non-invasive and highly sensitive and specific for the diagnosis of proximal lower extremity DVT.⁵¹ Full compressibility of either the femoral or popliteal veins excludes proximal DVT⁵¹ when compared to the gold standard demography; CUS has a sensitivity of 97% to 100% and a specificity of 98% to 99% for the detection of proximal thrombosis. Ultrasonography is less accurate in the diagnosis of distal calf vein thrombosis.^{51,52} Whether high-risk critically ill patients should be systematically screened for DVT using CUS, given the high incidence of DVT and limitation of clinical examination, is unresolved.^{13,17}

Upper extremity deep venous thrombosis (UEDVT) accounts for approximately 4% of the venous thromboembolic events.⁵³ Primary UEDVT makes up one third of all UEDVTs. Primary UEDVTs appear to be associated with inherited thrombophilic conditions, and the risk markedly increased to 14-fold when oral contraceptives were used.⁵⁴ Catheter UEDVTs are more associated with the placement of a central venous catheter, and these patients are more likely to be inpatients than outpatients, as demonstrated by a large registry.⁵⁵ In addition, patients with cancer have an increased occurrence of UEDVT when a central venous catheter is placed in these areas.⁵⁵ Catheter-related UEDVT may have a higher pulmonary embolic potential than primary UEDVT.⁵²

PATHOPHYSIOLOGY

Nearly two thirds of patients who die from pulmonary thromboembolism die within 1 hour of presentation, but anatomically massive pulmonary emboli (>50% obstruction of the pulmonary circulation) are responsible for only half of the deaths. The term *major pulmonary thromboembolism* has been used to describe any pulmonary thromboembolus that results in a hemodynamically significant event.¹ In patients with pulmonary thromboembolism, hemodynamic presentation is an important predictor of survival. The Urokinase Pulmonary Embolism Trial (UPET) demonstrated that the presence of hemodynamic decompensation was associated with a sevenfold increase in mortality rate.⁵⁶ ICOPER confirmed these results by demonstrating a fourfold increase in mortality rate for those patients with hemodynamic instability.³ Because of the associations between outcome from pulmonary thromboembolism and shock or hypotension, aggressive intervention in patients thought to have pulmonary thromboembolism has given rise to the term *golden hour*, during which timely diagnosis and treatment are paramount.¹

HEMODYNAMIC CONSEQUENCES

The principal pathophysiologic effects of pulmonary thromboembolism result from the acute impaction of material into pulmonary circulation and the resulting vascular obstruction and humoral mediator release as depicted in [Figure 44.1](#).⁵⁷ In nonthrombotic obstruction of the pulmonary vasculature, obliteration of 60% to 70% of the vascular tree is required to cause an elevation of the pulmonary artery pressure. In contrast, only 30% of the vascular tree must be obstructed in pulmonary thromboembolism for elevation of the pulmonary artery pressure to be achieved.^{58,59} Therefore, factors other than simple mechanical obstruction of the pulmonary vascular system play a role in the elevation of the pressures in the pulmonary vasculature during pulmonary thromboembolism.

The production of platelet-derived vasoconstrictors may play a role in augmenting the increase in pulmonary vascular resistance (PVR) ([Fig. 44.2](#)).^{57,58,60} Thromboxane A₂ (TxA₂) is a potent vasoconstrictor and is the end product of arachidonic acid metabolism. TxA₂ is produced by endothelial cells, and even in greater quantities by platelets in response to platelet aggregation. It has been demonstrated that there is increased production of TxA₂ in the early phase of PE, which contributes to the PVR elevation and may be attenuated by cyclooxygenase (COX) inhibition in animal models.⁵⁷ Serotonin (5-hydroxytryptamine) is one of the most potent pulmonary vasoconstrictors. Infusion of serotonin in an animal model can actually simulate the signs and symptoms of PE. Like TxA₂, platelets are the primary source of serotonin production in PE. Serotonin antagonism can reduce PVR.^{57,60}

As shown in [Figure 44.1](#), the degree of mechanical obstruction, the interplay of neurohumoral mediators, and the patient's underlying cardiopulmonary status will dictate the degree of RVD. A rapid rise in the pulmonary artery resistance produces a significant rise in right ventricular (RV) afterload, thereby causing RV dilatation. The dilation

There appears to be nearly an exponential increase in VTE events with age.²⁹ The elderly demonstrate an incidence of 300 to 500 cases/100,000 persons compared to 30 cases/100,000 of persons age 25 to 35 years.²⁹ A longitudinal study of 855 men followed from the ages of 50 to 80 years demonstrated the cumulative incidence of a VTE event was 0.5% by the age of 50 years and increased to 10.7% by the age of 80 years.³ The risk of VTE recurrences increases with age. In the elderly the PE rates are rising faster than the DVT rates; thus, a VTE event in an elderly person is more likely to be a PE, with its potential lethality.^{3,30}

Anderson and Spencer³¹ reviewed multiple risk factors associated with a diagnosis of VTE and found that the risk factors were not equal in their impact on VTE occurrence. The strongest risk factors were hip and leg fractures, major general surgery, hip or knee replacement, major trauma, and spinal cord injury. Moderate risk factors included arthroscopic knee surgery, central venous lines, chemotherapy, congestive heart failure, hormonal replacement or oral contraceptives, cancer, pregnancy, thrombophilia, and prior VTE.³¹ Heit and associates³² found that the hospital setting, nursing home, or other chronic facility confinement was an independent risk factor for the VTE. This is most likely reflective of the various degrees of immobility that these patients experience.

Several acquired and inherited hypercoagulable states have been shown to increase the risk of VTE and are collectively known as thrombophilia. Major acquired hypercoagulable conditions include malignancy, myeloproliferative disorders, and antiphospholipid syndrome (APS).³³ DVT, the most common manifestation of the APS, occurs in 29% to 55% of patients with the syndrome, and about half of these patients have pulmonary emboli.³⁴⁻³⁶

The occurrence of a VTE event in a young adult alerts the clinician to the potential of an underlying inheritable thrombophilic condition. Nearly half the patients with a VTE event before the age of 45 have an associated inherited disorder.³³ Factor V Leiden mutation causing resistance to

activated protein C is the most common inherited risk factor. Factor V Leiden mutation is present in up to 5% of the normal population and is the most common cause of familial thromboembolism.³³ Factor V Leiden mutation appears to be more associated with the development of DVT rather than PE.³⁷ Primary or acquired deficiencies in protein C, protein S, and antithrombin III are other risk factors and their thrombotic expression is variable.³³

Several primary disorders are associated with a high risk for fatal VTE. Patients frequently present with massive PE, and ICU admission and management is required. From the RIETE registry, risk factors of immobilization secondary to neurologic disease, cancer, and cardiopulmonary disorders had two- to threefold increased risk for fatal PE.³⁸ In hospitalized cancer patients, VTE is the second leading cause of death.³⁹ The risk of VTE in cancer patients undergoing surgery is three to five times greater than that in surgical patients without cancer. Moreover, cancer patients with symptomatic DVT exhibit a high risk of recurrent VTE.⁴⁰ Heart failure is a frequent admission diagnosis in the coronary care unit. In patients with severe heart failure (ejection fractions less than 30%) PE is a major cause of morbidity and mortality rates.^{41,42} Among 198 patients with severe heart failure in the coronary care unit, 9.1% developed PE during their hospitalization, despite a majority receiving thromboprophylaxis.⁴¹ In an autopsy series of cardiac patients nearly a quarter had PE and the diagnosis was unsuspected in 82% of the patients.⁴³ Acute exacerbation of chronic obstructive pulmonary disease (COPD) is a common reason for admission to the general hospital ward service and the ICU. Increase work of breathing leads to immobility, which is a risk factor of DVT. In a prospective cohort of 196 patients with COPD exacerbation, all patients had ultrasonography of the lower extremities performed. Among the 196 patients, 21 (10.7%) had DVT and the majority was asymptomatic.⁴⁴ Moreover, hospitalized patients with unexplained exacerbations of COPD, when routinely evaluated, show demonstrated PE in 25% to 29%.^{45,46}

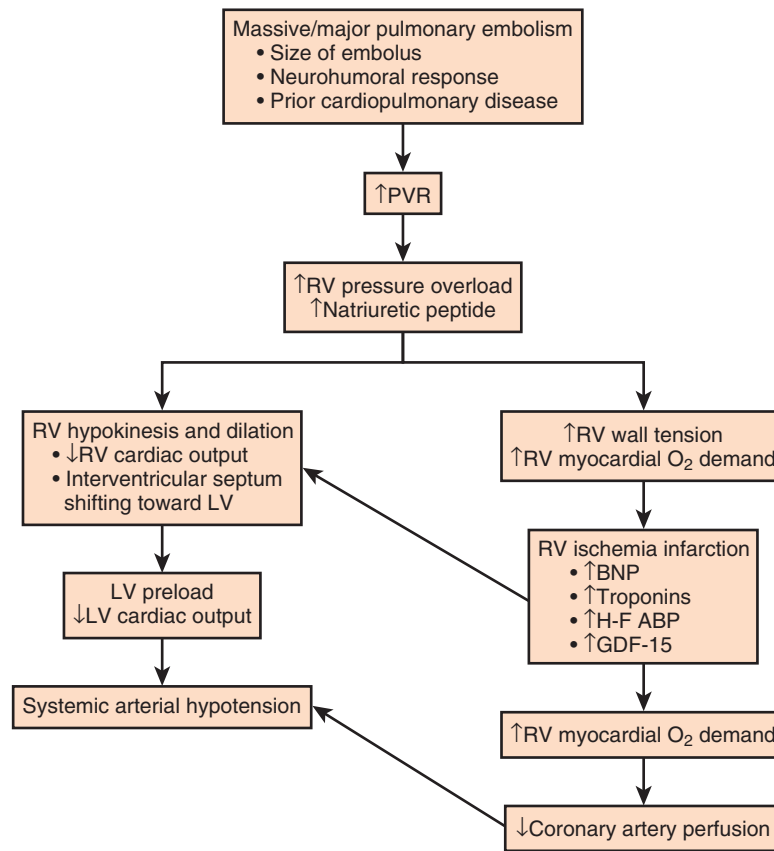

Figure 44.1 The pathophysiology of acute massive/major pulmonary embolism. GDF-15, growth differentiation factor-15; H-FABP, heart type fatty acid binding protein.

Figure 44.2 Platelet-derived vasoactive factors influencing pulmonary vascular resistance.

of the right ventricle results in shifting of the interventricular septum into the left ventricle, decreasing left ventricular (LV) preload.⁶¹⁻⁶³ Moreover, RV dilation potentially promotes an increase in constrictive forces by the pericardium, leading to reduced LV compliance. Decreasing LV preload and compliance subsequently lead to lowering of the cardiac output and systemic hypotension with resultant decrease in aortic perfusion pressure and decreasing right coronary perfusion pressure.^{64,65} A compromised and burdened right ventricle is a direct result of oxygen demand outstripping

oxygen supply, creating an ischemic environment for the right ventricle. The functional status of the cardiopulmonary system is very important in the initial hemodynamic presentation and is a major determinant of short- and long-term outcome.⁶⁶ In patients without cardiopulmonary disease the anatomic and humoral obstruction must be 75% or greater to cause a mean pulmonary artery pressure (MPAP) of 40 mm Hg or higher, which is not sustainable; even the previously healthy heart may proceed to cardiovascular collapse and fail.⁶⁶ Right atrial pressure (RAP)

elevation occurs when the MPAP is 30 mm Hg or higher and obstruction exceeds 35% to 40%.⁶⁷ Many patients who have a pulmonary embolic event have underlying cardiopulmonary disease. In these patients cardiopulmonary deterioration (CPD) may occur with a lesser degree of vascular obstruction.⁶⁶ This is illustrated by the UKEP (Urokinase-Embolie Pulmonaire) Trial in which an initial presentation of shock with acute PE was seen in 56% of patients who had prior cardiopulmonary disease compared to 2% without cardiopulmonary disease. Obstruction of greater than 50% was uncommon.⁶⁸

RESPIRATORY CONSEQUENCES

Hypoxemia is the most common gas exchange abnormality in patients. However, the PaO_2 and alveolar-arterial (A-a) gradient have been reported to be normal in approximately 30% of patients with PE.⁶⁹ Figure 44.2 summarizes the gas exchange abnormalities as a result of the pulmonary embolic event. Ventilation-perfusion mismatch and low mixed venous oxygen levels are the prevalent causes of hypoxemia.^{70,71} As pulmonary artery pressures increase, right-to-left flow across a patent foramen ovale (PFO) may occur. Endothelial damage may result from hypoxic exposure and further lead to pulmonary vasoconstriction. Hypoxemia may even promote a prothrombotic and antifibrinolytic effect.⁵⁷

In acute PE an increase in alveolar dead space impairs CO_2 elimination; however, the increase in minute ventilation results in hypocapnia. In patients with massive PE there can be a paradoxical elevation of the Paco_2 as a result of a marked increase in dead space ventilation.⁷² In PE patients because of an increase in alveolar dead space there is a reduction in alveolar CO_2 content, which can be detected by capnography by a reduction in the capnographic waveform area. In one study, PE patients significantly demonstrated a reduction in the capnographic waveform area when compared to patients without PE.⁷³ There is widening of the $\text{PETCO}_2\text{-Paco}_2$ gradient. Bedside PETCO_2 coupled with a Wells score has been shown to have a high negative predictive value.⁷⁴

CLINICAL PRESENTATION

The signs and symptoms of acute PE are at best nonspecific. The presence of syncope, current DVT, hemoptysis, leg swelling, active cancer, surgery, leg pain, and shock each marginally increases the probability of PE. Further, the absence of dyspnea or tachycardia marginally reduces the probability of PE.⁷⁵

Approximately 50% of patients with acute PE present to the emergency department. In the Emperor Registry, among 1880 documented PE patients from 22 U.S. emergency departments, the most common presenting signs and symptoms were dyspnea at rest (50%), pleuritic chest pain (39%), dyspnea with exertion (24%), and syncope, which occurred in 5% as the initial presentation of acute PE. Only 58 patients (3%) had systolic blood pressures of 90 mm Hg or lower on presentation.⁷⁶

Clinical prediction rules have been used in the emergency department setting to determine the pretest

probability of acute PE.⁷⁷ The most widely known prediction model has been the Wells score and it can allow for a dichotomous classification.^{78,79} Other prediction scores have been used, such as the Geneva and the modified Geneva.^{77,78} All prediction scores appear to have similar accuracy but are influenced by the local prevalence of PE. The clinical prediction scores are enhanced in identifying the patient with low probability of PE coupled with low D-dimer value.⁷⁹

CLINICAL PRESENTATION ON ADMISSION TO THE INTENSIVE CARE UNIT

In patients admitted to the ICU with PE the clinical manifestations may be more demonstrative, as shown in Table 44.2. In the Urokinase Pulmonary Embolism Trial (UPET), the clinical features of massive PE were evaluated. Sudden

Table 44.2 Clinical Signs and Symptoms of Acute Pulmonary Embolism Potentially Requiring Intensive Care Unit Management

Clinical Variable	Frequency (%)		p Value
	Submassive PE	Massive PE	
Symptoms	78	86	<0.01
Dyspnea	85	97	<0.01
Pleuritic pain	50	70	<0.01
Apprehension	20	44	<0.01
Altered mental status	4	17	<0.05
Diaphoresis	47	62	<0.01
Syncope	85	81	
Signs	51	50	
Tachycardia (heart rate >100 beats/min)	47	66	
Tachypnea (respiratory rate >20 breaths/min)	81	87	
Fever (>37.5°C)	51	50	
Deep venous thrombosis	47	39

Shock		12*	
Cardiac arrest (PEA)			

PE, pulmonary embolism; PEA, pulseless electrical activity.

*Adapted from Stein PD, Willis PW III, DeMets DL: History and physical examination in acute pulmonary embolism in patients without pre-existing cardiac or pulmonary disease. *Am J Cardiol* 1981;47:218-223.

unexplained onset of dyspnea was the most common symptom and was present in 80% of the patients. A majority of the patients had a well-defined risk factor. Tachypnea and tachycardia were present in 88% and 63% of the patients, respectively. Accentuated second heart sound was noted in 67%, and S₃ or S₄ gallop was present in 47%. Clinical shock was noted in 12%.⁸⁰ Syncope can occur. Retrosternal non-pleuritic chest pain may mimic the pain experienced with a myocardial infarction and represent demand ischemia of the right ventricle. The differential diagnosis of pulseless electrical activity (PEA) is massive PE and should be expected when there is a known major risk factor.

The signs and symptoms of submassive PE will depend upon the degree of RVD. Dyspnea may be progressive over the last 4 to 6 days. Chest pain can be either pleuritic or nonpleuritic in nature. If pulmonary infarction occurs as result of distal embolization, then hemoptysis may occur. From the PIOPED II database, 92% of patients with main or lobar pulmonary emboli had dyspnea or tachycardia in contrast to segmental emboli dyspnea and tachycardia, where 65% had these findings.^{81,82}

Patients with massive PE and shock manifest systemic hypotension, poor perfusion of the extremities, tachycardia, and tachypnea. In addition, patients appear weak, pale, diaphoretic, oliguric, and develop altered mental status. The patient may be hypoxemic and require high flow oxygen or urgent intubation and mechanical ventilation. Varying degrees of RVD may be observed. The presence of jugular venous distention, with and without inspiratory collapse, RV heave, summation gallop, accentuated P₂, and presence of tricuspid regurgitation represent the impact the embolus has had on pulmonary vasculature and RV function. If a central line is placed via the subclavian or jugular route, the ScvO₂ is usually less than 65%.

RECOGNITION OF PULMONARY EMBOLISM DURING INTENSIVE CARE UNIT ADMISSION

When a patient is admitted to the ICU for a non-PE-related clinical diagnosis, the abrupt and unexplained occurrence of some combination of chest pain, dyspnea, tachypnea, hypotension, and hypoxemia should raise the suspicion of PE. Unexplained fever with and without mild leukocytosis could represent a possible VTE event.⁸³ Hemoptysis can occur as a result of small distal pulmonary emboli causing alveolar hemorrhage. If PE occurs while the critically ill patient or postoperative patient is on mechanical ventilation, the clinical suspicion and confirmation can be difficult. An increase in minute ventilation dead space or an increase in supplemental oxygen may be clues to an embolic event. If the patient has end-tidal CO₂ (PETCO₂) monitoring an increase in the PaCO₂-PETCO₂ gradient may occur.⁷³

DIAGNOSTIC TESTING FOR PULMONARY EMBOLISM

ARTERIAL BLOOD GAS MEASUREMENT

Hypoxemia and an increased alveolar-arterial gradient are usually seen in PE but can be normal in about 14% and are most likely the result of small embolic events.^{84,85} The initial

acid-base disturbance is a respiratory alkalosis, which may evolve to a metabolic (lactic) acidosis as hypotension and shock ensue. A linear relationship between PE severity and Pao₂ in patients without prior cardiopulmonary disease has been described. In the UPET and PIOPED trials 12% and 19% of patients, respectively, had Pao₂ 80 mm Hg or greater.⁸⁶ Hypocarbica is usually present with acute PE because of hyperventilation, but hypercapnia can occur with large PEs producing increased dead space.^{87,72}

CHEST RADIOGRAPHY

The chest radiograph is abnormal in most cases of PE; however, radiographic findings possess inadequate sensitivity to rule out PE. Common radiographic abnormalities include atelectasis, pleural effusion, parenchymal opacities, and elevation of a hemidiaphragm. Radiographic findings of pulmonary infarction often show a wedge-shaped, pleural-based triangular opacity with an apex pointing toward the hilus (Hampton hump). Focal oligemia or decreased vascularity has been known as the Westermark sign. These findings are suggestive of PE but are infrequently prospectively observed.^{88,89} Radiographic findings of RVD may include a prominent central pulmonary artery (knuckle sign) and cardiomegaly. In one large prospective cohort of PE patients a normal chest radiograph was found in 24% of the patients.⁸⁹ A normal-appearing chest radiograph in a patient with severe dyspnea and hypoxemia, is suggestive of a pulmonary embolic event.

ELECTROCARDIOGRAPHY

In 1935 McGinn and White first described the association between acute PE and specific electrocardiogram (ECG) changes when they noted the S₁Q₃T₃ pattern in seven patients with acute cor pulmonale.⁹⁰ A normal ECG can occur with PE in a frequency ranging from 9% to 30%. The most common ECG abnormalities in the setting of PE are tachycardia and nonspecific ST-T wave abnormalities. The classic findings of right-sided heart strain and acute cor pulmonale are tall, peaked P waves in lead II (P pulmonale); right-axis deviation; right bundle branch block; and an S₁Q₃T₃ pattern. Only 20% of patients with proven PE have any of these classic ECG abnormalities.⁹¹⁻⁹³ T-wave inversion in the precordial leads representing subepicardial ischemia may be seen. The presence of this ECG finding is associated with increased degree of vascular obstruction and elevation of the pulmonary artery (PA) pressure.⁹⁴ The new onset of atrial fibrillation has been thought to be associated with a pulmonary embolic event. In a recent study the occurrence of atrial fibrillation did not in general increase the probability of PE.⁹⁵ However, if chest pain were the only symptom, the presence of atrial fibrillation increases the probability of PE (odds ratio [OR] 2.42, 95% confidence interval [CI] 0.97-6.07).

D-DIMER ASSAY

The serum D-dimer is a degradation product produced by plasmin-mediated proteases of cross-linked fibrin. D-dimer is measured by a variety of assays. These assays are categorized as quantitative, semiquantitative, qualitative

rapid enzyme-linked immunosorbent assays (ELISAs); quantitative and semiquantitative latex; and whole-blood assays. The quantitative rapid ELISAs are the best assays to use in terms of sensitivity and likelihood ratio.⁹⁶ When clinical prediction scores indicate that the patient has a low or moderate pretest probability of PE, D-dimer testing is useful to further define the likelihood of PE. Negative results on a high-sensitivity D-dimer test in a patient with a low pretest probability of PE (Wells rule) are associated with a low likelihood of VTE and reliably exclude PE.⁹⁷ In a large prospective, randomized trial in patients with a low probability of PE who had negative D-dimer results, not performing additional diagnostic testing was not associated with an increased frequency of symptomatic VTE during the subsequent 6 months.⁹⁸

D-dimer testing loses its ability to predict the likelihood of PE in older patients and in the presence of cancer, pregnancy, and various inflammatory or infectious disorders. If the pretest probability for PE is high, D-dimer testing should not be performed and objective testing should be done.⁹⁶

Combining D-dimer results with measurement of the exhaled end-tidal ratio of carbon dioxide to oxygen ($PETCO_2/PO_2$) can be useful for diagnosis of PE. Kline and colleagues demonstrated in moderate-risk patients a positive D-dimer (>499 ng/mL) and a $PETCO_2/PO_2$ less than 0.28 significantly increased the probability of finding segmental or larger PE on computed tomography (CT) multidetector-row pulmonary angiography.⁹⁹ In contrast, a $PETCO_2/PO_2$ greater than 0.45 predicted the absence of segmental or larger PE.

DUPLEX COMPRESSION ULTRASONOGRAPHY

Currently, DVT is largely diagnosed by duplex CUS. When using CUS, the ultrasonographic transducer pressed against veins shows they are easily compressed, but the muscular arteries are extremely resistant to compression. Where DVT is present, the veins do not collapse completely when pressure is applied using the ultrasonographic probe.¹⁰⁰⁻¹⁰²

Before an ultrasonographic scan can be considered negative, the entire deep venous system must be examined using centimeter-by-centimeter compression testing of every vessel. The risk of a DVT event following a single whole leg CUS in 3 months is 0.57% (95% CI 0.25-0.89).¹⁰³

CUS is associated with a sensitivity of 97% for proximal DVT, 72% for distal DVT, and a specificity of 94%.¹⁰⁴ In a meta-analysis of the role of CUS in DVT, CUS alone had a sensitivity of 93.8% (92.0-95.3%) for proximal DVT, 56.8% (49.0-66.4%) for distal DVT, and specificity of 97.8% (97.0-98.4%).¹⁰⁵

VENTILATION-PERFUSION NUCLEAR SCANS

The \dot{V}/\dot{Q} scan has a limited role in the diagnosis of acute PE in the ICU, although its diagnostic accuracy is no different from that in non-critically ill populations.¹⁰⁶ Because of the advancing technology of CT scanning, the lung scan is used in the critical care units in special circumstances such as renal insufficiency or in the patient who is not intubated and capable of transport from the ICU to the nuclear medicine suite for a full view scan. If the institution has a portable lung scanner this can be used in the ICU but the

number of images is reduced when compared to the standard \dot{V}/\dot{Q} scan.

A high-probability scan, as shown in Figure 44.3, is sufficient diagnostic evidence of PE to begin anticoagulation therapy, and a normal \dot{V}/\dot{Q} scan is considered sufficient evidence to exclude PE. However, the frequency of low- or intermediate-probability scans (indeterminate scans) can be as high as 50% to 70%, with a 10% to 50% probability of PE. Therefore, it is impossible to initiate anticoagulation therapy based on this indeterminate lung scan probability. In the first PIOPED study, only 40% of patients with PE had a high-probability \dot{V}/\dot{Q} scan result, whereas another 40% of patients with PE had an indeterminate result and 14% had a low-probability result. A high-probability \dot{V}/\dot{Q} scan had a positive predictive value of 88% in patients without prior history of PE. The combination of a high clinical probability with the high-probability lung scan resulted in a 96% positive predictive value. The negative predictive value of a low-probability scan was 88% and improved to 96% when combined with a low clinical probability. Thus, a low-probability scan with a low clinical probability score rules out PE as definitively as a normal scan. Finally, 39% of the patients had intermediate scans and 32% of these patients had angiographically proven PE.^{14,107}

Preexisting cardiopulmonary disease diminishes the clinical utility of \dot{V}/\dot{Q} scans by increasing the prevalence of nondiagnostic scans. Nondiagnostic scans are more likely to occur in patients with preexisting cardiopulmonary disease. Lung scans are not useful to either establish or rule out the diagnosis of PE in more than 80% of cases. A similar disadvantage of \dot{V}/\dot{Q} lung scans is noted in critically ill patients with prior cardiopulmonary disease. Nevertheless, \dot{V}/\dot{Q} lung scans can be performed in the critically ill, even if patients are receiving mechanical ventilation, and chest radiographic abnormalities can be used as a surrogate of ventilation defects. Despite the limited ventilation component under positive-pressure respiration, the perfusion component is not significantly affected by mechanical ventilation. \dot{V}/\dot{Q} scans remain a useful tool in patients with contraindications to pulmonary angiography or CT angiography.^{108,109}

MULTIDETECTOR COMPUTED TOMOGRAPHY SCAN OF THE CHEST

The PIOPED II study firmly established the role of CT pulmonary angiography (CTPA) and largely replaced ventilation-perfusion (\dot{V}/\dot{Q}) lung scintigraphy as the main imaging modality in suspected PE.¹¹⁰ The technology is continually evolving and its use is widespread. As illustrated in Figure 44.4, CTPA provides direct visualization of emboli throughout the pulmonary arterial vasculature. The advantage of CTPA over pulmonary angiography and lung scan is the discovery of an alternative diagnosis when PE is not found on CTPA. In one study, an alternative diagnosis was established in 57% of patients who did not have a PE.¹¹¹ Currently, CTPA is the “gold standard” for PE diagnosis. A meta-analysis of 23 studies with 4657 patients with a negative CTPA who did not receive anticoagulation showed a 3-month rate of subsequent VTE of 1.4% (95% CI 1.1-1.8) and a 3-month rate of fatal PE of 0.51% (0.33-0.76), which compares favorably with the results noted after a normal “gold

Figure 44.3 High-probability ventilation-perfusion lung scan in a patient with submassive pulmonary embolism and right ventricular strain. Large left lung perfusion defects with a right upper lobe apical perfusion defect are present. Ventilation is normal.

standard” invasive contrast pulmonary angiogram.¹¹² The increased use of CTPA raises concerns about the increased incidence of cancer attributable to radiation.¹¹³ For this reason, combined use of CTPA and CT leg venography should not be performed because the latter adds little to diagnostic utility. In the PIOPE II trial, no patient with PE or DVT would have been undiagnosed if imaging of the pelvic and proximal leg veins had been omitted.^{107,110}

MAGNETIC RESONANCE IMAGING

In the PIOPE II study, CT angiography of the chest, as many as 25% of patients had a contraindication for the test. Preexisting renal failure and pregnancy were the primary conditions that prevented this mode from being used as the primary test for the evaluation of PE.¹¹⁰ Thus, gadolinium-enhanced magnetic resonance pulmonary angiography (MRA) could potentially be used to diagnose PE because it is devoid of radiation. The accuracy of this technique combined with magnetic resonance venography (MRV) has

been studied in the prospective, multicenter PIOPE III accuracy study. The proportion of technically inadequate images ranged from 11% to 52% across the seven participating centers. Technically adequate MRA had a sensitivity of 78% and a specificity of 99%, whereas technically adequate MRA and MRV had a sensitivity of 92% and a specificity of 96%. However, 194 (52%) of 370 patients had technically inadequate results, which substantially restricts its clinical use.¹¹⁴

RISK STRATIFICATION

Death from an embolic event almost always results from hemodynamic deterioration due to an abrupt rise in pulmonary vascular resistance overwhelming the contractile power of the right ventricle. Progressive hemodynamic and respiratory deterioration characterizes the clinical presentation of major or massive PE and is seen in approximately 5% of PE patients.² Patients can be categorized as having submassive

Figure 44.4 Extensive bilateral lobar pulmonary emboli.

PE. Risk stratification becomes important to identify this group of patients who present with relative hemodynamic stability but exhibit varying degrees of RVD. Risk stratification schemes in normotensive patients center on RV function assessment after an embolic event and identify patients who may be at risk for progressive hemodynamic deterioration. Approximately 50% of patients who are normotensive have varying degrees of RVD and 10% will die. The European Society of Cardiology recommends a classification of PE into high-risk and non-high-risk groups. The high-risk groups represent the massive or major PE presentations. The non-high-risk group is further subdivided into intermediate risk in which the mortality rate ranges between 3% and 15% and a low-risk group in which the mortality rate is less than 3%. Initial therapeutic interventions are greatly influenced by risk stratification that includes clinical scoring systems, laboratory data, and imaging.¹¹⁵⁻¹¹⁷

The presence of RVD is a predictor of the increased risk of embolic-related adverse events and mortality rates when compared with patients without RVD.² Patients who present with circulatory shock usually have severe RVD and have mortality rates up to 65%.^{1,2,115} In PE patients with normal hemodynamics and evidence of RVD the mortality rates can range from 8% to 14%. Several registry studies have observed that the frequency of RVD in normotensive patients is approximately 40%.^{116,117} In PE patients with initial normal hemodynamics and no RVD the mortality rate is low (0-3%).

CLINICAL AND HEMODYNAMIC PARAMETERS

The initial hemodynamic presentation of PE is the most powerful predictor of outcome, as illustrated in [Figure 44.5](#). Arterial hypotension at the time of PE presentation is an early predictor of death. In the 2392 patients from the ICOPER study, the 90-day mortality rates were 52.4% in patients with systolic arterial blood pressures below 90 mm Hg, and 14.7% in those patients who had preserved arterial blood pressures. In addition, comorbid conditions increase the risk of adverse clinical events, even in the presence of anatomically small PE. In the ICOPER findings, age over 70, congestive heart failure, cancer, and chronic lung disease were identified as independent predictors of

Figure 44.5 Pulmonary embolism mortality rate based on initial hemodynamic presentation.

3-month mortality risk, with approximately twofold increase in the risk of death.² In one study, altered mental status at presentation was associated with a sevenfold increase in risk of adverse outcome. Altered mental status most likely reflected decreased cardiac perfusion or hypoxia. In the same study the initial presentation of shock was associated with a threefold increase in risk of 30-day adverse outcome (death, secondary shock, or recurrent PE).¹¹⁷

Patients can be clinically risk stratified by the use of a clinical scoring system known as the Pulmonary Embolism Severity Index (PESI), which also has a simplified version.^{118,119} This prognostic model was developed by Aujesky and colleagues (Table 44.3) using a large database of hospitalized PE patients from which they derived and validated a prediction rule that identified acute PE patients with low to high risk for fatal PE and adverse events. Using 11 variables of predictors, five distribution categories emerged looking at inpatient fatality, 30-day all-cause mortality rate, and the adverse outcomes of nonfatal cardiogenic shock or cardiopulmonary arrest. Class I to class III all-cause mortality rates ranged between 0% and 3.1%, although class IV to class V all-cause mortality rates were between 10% and 24%. This score has an excellent negative predictive value and readily identifies low-risk patients but suffers in the attempt to predict patients at high risk for adverse events.¹¹⁹ A more simplified PESI score has been developed and has a high negative prediction value.¹²⁰

In patients with symptomatic acute PE, the presence of DVT may have prognostic significance. In a prospective study by Jiménez and coworkers, among 707 patients diagnosed with acute PE, 51.2% had concomitant DVT and 10.9% had PE-specific fatality at a 3-month follow-up. Patients with PE with the presence of DVT at the time of diagnosis had an adjusted hazard ratio (HR) of 2.05% (95% CI 1.24 to 3.38) and PE-specific fatality-adjusted HR of 4.25 (95% CI 1.61 to 11.25). These findings were validated by a large international registry trial (RIETE) that again demonstrated a significant prediction of all-cause mortality rate

Table 44.3 Pulmonary Embolism Severity Index (PESI)**Scoring**

Predictor	Points Assigned
Age	Age, in years
Male gender	+10
Cancer	+30
Heart failure	+10
Chronic lung disease	+10
Pulse >110 beats/min	+20
Systolic blood pressure <100 mm Hg	+30
Respiratory rate >30 breaths/min	+20
Temperature <36° C	+20
Altered mental status	+60
Arterial SaO ₂ <90%	+20

Risk Classification

Class and Distribution	Score Range	Inpatient Mortality Rate (%)	30-Day Mortality Rate (%)	Nonfatal Cardiogenic Shock or Cardiopulmonary Arrest
Class I (19.4%)	<65	0.8	1.1	0.4
Class II (21.5%)	65-85	1.8	3.1	1.3
Class III (21.7%)	85-105	4.2	6.5	2.1
Class IV (16.4%)	106-125	5.9	10.4	1.9
Class V (21.0%)	<125	15.8	24.5	4.6

and PE-specific mortality rate when the concomitant DVT was present during the acute embolic event. These results suggest that patients with symptomatic acute PE have an increase in all-cause mortality rate, PE-related death, and recurrent VTE over a 3-month period if at the time of PE a diagnosis of proximal DVT is also present.¹²¹

ELECTROCARDIOGRAM

Several studies have demonstrated that ECG signs of RV strain correlate with the presence of RVD.^{122,123} A study by Punukollu and associates showed that T-wave inversion in leads V₁ to V₃ had a specificity of 88% and diagnostic accuracy of 81% for RVD in acute PE.¹²⁴ Daniel and colleagues developed an ECG scoring system based on typical features of acute PE such as presence of right bundle branch block (RBBB), T-wave inversions, and additional features of right-sided heart strain that predicted severe pulmonary hypertension (sPAP >50 mm Hg) with a specificity of 97.7% if the patient's "ECG score" is 10 or greater.¹²⁵ The ECG may also be a tool for risk stratification of normotensive acute PE patients. In a study by Vanni and coworkers among 306 patients with documented PE 130 (34%), patients demonstrated ECG findings of right-sided heart strain. In this study ECG findings of right-sided heart strain were defined as incomplete or complete RBBB, S₁Q₃T₃, or inverted T waves in the precordial leads V₁, V₂, and V₃. For this study only one of these ECG patterns had to be present. The investigators demonstrated that the presence of RV strain on the initial ECG was associated with clinical deterioration and death (HR 2.58) in normotensive PE patients.¹²²

CARDIAC BIOMARKERS

Biomarkers are relied on in the risk stratification of patients with PE. Tests for biomarkers are widely available and there is usually a quick turnaround from the clinical laboratory. Caution must be taken on the interpretation of these biomarkers. It is important for the critical care clinician to understand the clinical issues that impact the interpretation of the biomarkers and understand the negative and positive predictive values.¹¹⁵ Elevations of brain natriuretic peptide (BNP) and troponin occur in many patients with PE and correlate with magnitude of RVD.

ECHOCARDIOGRAPHY

The echocardiogram has become the main imaging modality to assess RV structure and function. In addition, pulmonary artery pressures can be estimated. Most hospitals in the United States have portable echocardiographic technology allowing for serial assessment of the impact of treatment on RVD. In hemodynamically stable patients with PE, 20% to 40% will have some echocardiographic finding of RVD.^{116,117} Box 44.1 illustrates the echocardiographic finding of acute PE. Toosi and colleagues performed a quantitative risk assessment of various echocardiographic measurements of RVD in acute PE. For in-patient mortality rate the positive predictive values range between 11% and 20% and the negative predictive values are 97% to 100%.¹⁴⁰ The major drawback with the role of the echocardiographic definition of RVD of acute PE is that it lacks standardization. There is no clear agreement on which of the echocardiographic

BRAIN NATRIURECTIC PEPTIDE

The heart will release natriuretic peptides as result of ventricular volume overload. Ventricular stretch results in cellular production of proBNP. This peptide is subsequently cleaved to the biologically active BNP and the inactive N-terminal fragment (NT-proBNP).¹²⁶ Both BNP and NT-proBNP can be measured clinically and have been validated as diagnostic and prognostic markers of ventricular stretch in multiple conditions, including congestive heart failure, pulmonary hypertension, and acute PE.¹²⁷ Elevated concentrations of BNP distinguish patients with PE at higher risk of complicated in-hospital course and death from those with low BNP levels. Both BNP and NT-proBNP have been extensively investigated as prognostic markers in acute PE. In an early study, ten Wolde and colleagues¹²⁷ demonstrated in a prospective cohort of normotensive acute PE patients that those who died within 90 days had a significantly increased BNP level at the time of diagnosis compared with those patients who did not die in follow-up (245 pg/mL vs. 30 pg/mL, respectively). In addition, using a cut-off point of 75 pg/mL, these investigators reported that BNP had a positive predictive value of PE-related fatality of 17%, whereas the negative predictive value for death was 99%.¹²⁷ As will be seen for most of the prognostic markers for acute PE, the investigators noted that BNP was able to identify those at low risk of adverse outcomes but did not have good specificity (many false-positives) in identifying those who were likely to die from their PE.

Normal levels of BNP have a high negative predictive value for an elevated level of BNP or NT-proBNP as a risk factor for short-term fatality and overall short-term complicated clinical outcome, and an indicator of RVD in patients with acute PE. This is illustrated by the study by Kucher and colleagues,¹²⁸ who investigated the prognostic capabilities of NT-proBNP in a prospective cohort of acute PE patients. In those suffering an adverse event (defined as a combined end point of in-hospital death or need for escalation of care, including cardiopulmonary resuscitation, mechanical ventilation, vasopressor, or thrombolysis), NT-proBNP was significantly higher compared with those who did not experience an adverse event (median of 4250 pg/mL vs. 121 pg/mL, respectively). An NT-proBNP cut-off point of 500 pg/mL yielded a negative predictive value for adverse outcome of 97% with a corresponding positive predictive value of adverse outcome of 45%.¹²⁸ In a meta-analysis of 13 studies by Klok and associates, they indeed demonstrate that increased BNP or proBNP was a risk factor for short-term fatality and adverse clinical events and a marker for RVD. However, the investigators caution against using this biomarker alone to justify more aggressive medical therapy, such as thrombolytic therapy.¹²⁹

CARDIAC TROPONIN

Serum troponins are widely available for the evaluation of diverse forms of myocardial injury. The assays are rapid and are well suited as a risk stratification tool. A number of studies and meta-analyses have evaluated the prognostic value of cardiac troponin I (TnI) or T (TnT) (determined by conventional assays) in acute PE.¹³⁰⁻¹³² Overall, the

elevation of cardiac troponin levels was associated with an adverse early outcome including fatality.

In hemodynamically (normotensive) stable patients with PE the incidence of elevated troponins can be as high as 40%.¹³³ As with the management of acute myocardial infarction, in a patient with acute PE, troponin levels must be obtained serially. The first troponin level in patients with PE may be normal, and subsequently levels will increase. This was illustrated in the study by Ferrari and colleagues who investigated the time course of TnT elevation in patients with acute PE. In a prospective cohort, they found that whereas 50% of normotensive patients with acute PE were found to have an elevated TnT, 5% of these patients had an initial normal TnT that became abnormal at the 6-hour analysis; moreover, 25% of those with an elevated TnT (0.01 ng/mL) died during the hospitalization compared with no patient dying who had a TnT value less than 0.01 ng/mL.¹³⁴

In a recent meta-analysis, Becattini and colleagues¹³² analyzed the prognostic usefulness of cardiac troponins in acute PE. In this meta-analysis of 20 studies, the investigators reported that 20% of patients with elevated troponins died, compared with 3.7% of patients with normal troponin levels. A high level of either TnT or TnI was associated with a fivefold increased risk of short-term death. The investigators noted that there were a multitude of different troponin assays and selected cut-off points used in the included reports, although results were generally consistent across studies. Most studies included in the meta-analysis defined an elevated troponin level as any value that was above the upper limit of normal for the individual troponin assay.¹³²

Combining biomarkers with imaging may enhance the prognostication of normotensive patients with acute PE. In one study, the presence of an elevated troponin, and echocardiographic evidence of RVD and the presence of a proximal DVT was associated with an increased 30-day mortality rate.¹³⁵

New generations of highly sensitive troponin (hsTnT) assays in patients with acute myocardial infarction have demonstrated excellent diagnostic performance and the potential to improve early risk stratification PE.¹³⁶

Other cardiac biomarkers are released in the systemic circulation when the myocardium is injured. Heart type fatty acid binding protein (H-FABP) is a cytosolic protein that is within cardiac myocytes that is released faster than cardiac troponins during injury. Studies have demonstrated that H-FABP has a good negative predictive value for adverse outcomes and, in one study, a 28% positive predictive value in patients with acute PE.^{137,138} Growth differentiation factor (GDF)-15 is a distant member of the transforming growth factor- β family. Under normal conditions, myocardium does not produce GDF-15, but its cardiac expression sharply increases after pressure overload and ischemia. The prognostic value of GDF-15 was investigated in a study including 123 patients with acute PE.²³ On multivariate analysis, cardiogenic shock on admission, cardiac TnI, and GDF-15 were independently associated with an adverse outcome at 30-day follow-up.¹³⁹ Further studies are needed to confirm these preliminary results.

Box 44.1 Echocardiographic Features of Acute Pulmonary Embolism

Global reduction of RV function
 RV dilation
 RV hypokinesis
 McConnell's sign (free wall hypokinesis sparing of the apex)
 Interventricular septal flattening
 "D-shaped" LV resulting from paradoxical septal motion
 RV/LV thrombus
 Dilated inferior vena cava without inspiratory collapse
 Pulmonary hypertension
 Tricuspid regurgitation with a jet velocity >2.6 m/sec
 Patent foramen ovale (PFO)—result of increased pulmonary artery pressures

LV, left ventricle; RV, right ventricle.

findings predicts adverse outcomes and fatality in normotensive submassive PE. However, an echocardiographic finding of right ventricle/left ventricle ratio of greater than 0.9 was found to be an independent risk factor of in-hospital death (OR 2.7% CI 1.7-6.0) in a large registry trial.¹⁴¹

In the ICOPER study that included 1035 PE patients with systolic arterial pressure 90 mm Hg or higher, an echocardiogram was performed within 24 hours of PE diagnosis. The incidence of RVD was 39% (405 patients). The 30-day survival rates were lower in patients with RV hypokinesis (84%) compared with those without RV hypokinesis (91%), HR 1.94 (CI, 1.41-3.16; $p \leq 0.001$). The negative predictive value of 30-day mortality rate of echocardiographic confirmation of RVD was 91%. The positive predictive value was 16%.²

In the assessment of RVD, if cardiac biomarkers are elevated, how well does this correlate with RVD on transthoracic echocardiography? A study by Logeart and coworkers found that a BNP level of less than 100 pg/mL had a negative predictive value of 100% and TnI of less than 0.10 ng/mL had a negative predictive value of 67% for the presence of RVD on echocardiography. Combining a BNP of greater than 100 pg/mL and TnI of greater than 0.10 ng/mL had a positive predictive value of 80% for the presence of RVD by echocardiography.¹⁴²

The echocardiogram can visualize free-floating right-sided heart thrombi. In the ICOPER study patients with this finding had a mortality rate of 21% compared with 11% in those without right-sided heart thrombi.¹⁴³ The detection of a patent foramen ovale or atrial septal defect by echocardiography may be a warning finding for the development of paradoxical embolization, which is associated with a risk of stroke and increased mortality rate.¹⁴⁴

For the evaluation of circulatory shock transesophageal echocardiography (TEE) is a useful diagnostic modality. In patients with massive PE who cannot undergo CTPA, when TEE is performed, it has a 60% to 80% sensitivity and a 95% to 100% specificity to diagnose acute PE. TEE has a 9% to 95% sensitivity and a 100% specificity in main pulmonary artery PE.¹⁴⁵ In patients with unexplained cardiac arrest or pulseless electrical activity (PEA), TEE has been shown to

identify acute massive PE. In a small study of 25 patients with PEA, TEE demonstrated eight (36%) patients with massive PE.¹⁴⁶

Echocardiography is an important diagnostic and prognostic tool in the management of patients with PE. Echocardiography also influences the therapeutic strategy based on cardiac hemodynamics and RV function. It is simple, quick, noninvasive, accurate, convenient, and safe, while providing critical information on the physiologic effects of PE on cardiac hemodynamics as well as RV size and function.

COMPUTED TOMOGRAPHY PULMONARY ANGIOGRAPHY

CT scans findings of right-sided heart dysfunction are illustrated in **Figures 44.6A and B**. The detection of RV enlargement by spiral chest CT has recently been evaluated in the risk stratification of patients with acute PE. Using measurements from a reconstructed CT four-chamber view, RV enlargement, defined as a ratio of RV to LV dimension of greater than 0.9, was a significant independent predictor of 30-day mortality rate.¹⁴⁶ In a recent multicenter study of 460 consecutive patients with multidetector CT confirmed PE a majority of the study cohort were hemodynamically stable and 50% had RVD at the time of diagnosis. Again, an RV/LV ratio of 0.9 or greater provided good correlation with RVD demonstrated by echocardiography. In addition, RVD found on multidetector CT was an independent risk factor for death and clinical deterioration. The investigators propose that multidetector CT scan potentially can be the single procedure, not only for diagnosis of PE but also for risk stratification. However, this assumption will require more validation studies.¹¹²

In hemodynamically stable patients with acute PE, assessing RV/LV ratio may be important in not only risk stratification but also the location of the emboli. In a recent multicenter study of 516 hemodynamically stable PE patients central localization of emboli was found to be an independent mortality risk factor, although distal localization was inversely associated with adverse events. Thus, anatomic findings by CT scan may be important in assessing risk in hemodynamically stable patients with pulmonary embolus.¹⁴⁷

Table 44.4 summarizes the various risk modalities used in risk stratification of acute PE.

THE MANAGEMENT OF ACUTE PULMONARY EMBOLISM**PHARMACOLOGIC MANAGEMENT**

The anticoagulation treatment for DVT and acute PE is essentially the same. Anticoagulation therapy does not dissolve the clot but prevents extension. Anticoagulation therapy indirectly decreases clot burden by allowing the natural fibrinolytic system to dissolve thrombus. When PE is suspected, if there is no contraindication, anticoagulation therapy should be started immediately while diagnostic studies are being performed.¹⁴⁸

Figure 44.6 **A**, Computed tomography (CT) scan findings of major pulmonary emboli with right ventricular dysfunction (RVD). **B**, CT scan findings of RVD (RV/LV ratio >0.09). **B** Hepatic reflux of contrast indicated significant RVD.

Table 44.4 Risk Stratification Determination in Acute Pulmonary Embolism

Risk Stratification Test	RV Dysfunction Potentially Present
Compression ultrasonography	Presence of proximal DVT
Natriuretic peptide	BNP >90 pg/mL NT-proBNP >500 pg/mL
Cardiac troponins	TnT >0.1 ng/mL TnI >0.4 ng/mL
Transthoracic echocardiography	Apical four-chamber view: RV/LV ratio >0.9 Qualitative RV systolic dysfunction
Chest computed tomography pulmonary angiogram (CTPA)	Reconstructed four-chamber view: RV/LV ratio >0.9
Electrocardiogram	New complete or incomplete RBBB Anteroseptal ST-segment elevation or depression Anteroseptal T-wave inversion

BNP, brain natriuretic peptide; DVT, deep venous thrombosis; LV, left ventricle; RBBB, right bundle branch block; RV, right ventricle.

UNFRACTIONATED AND LOW-MOLECULAR-WEIGHT HEPARIN

Heparins act by binding to the natural anticoagulant antithrombin, thereby accelerating the inactivation of thrombin by antithrombin and several other activated coagulation

factors. This mechanism of action will prevent extension of the thrombus. UFH is usually administered as an initial bolus, followed by a continuous intravenous infusion. Because of a large individual difference in the binding of heparins to plasma proteins, the doses should be adjusted to the results of the activated partial thromboplastin time (aPTT) or the anti-factor Xa (anti-Xa) activity.¹⁴⁹

The effectiveness of heparin therapy depends largely on achieving a critical therapeutic level of heparin within the first 24 hours of treatment. Nomogram dosing of heparin has been shown to achieve this goal.¹⁵⁰ The critical therapeutic level of heparin is 1.5 times the baseline control value or the upper limit of normal range of the aPTT. This level of anticoagulation is expected to correspond to a heparin blood level of 0.2 to 0.4 U/mL by the protamine sulfate titration assay and 0.3 to 0.6 by the anti-Xa assay.¹⁵¹ If intravenous UFH is chosen, an initial bolus of 80 U/kg or 5000 U followed by an infusion of 18 U/kg/hour or 1300 U/hour should be given, with the goal of rapidly achieving and maintaining the aPTT at levels that correspond to therapeutic heparin levels. Fixed-dose and monitored regimens of subcutaneous UFH are available and are acceptable alternatives.^{148,150}

Low-molecular-weight heparins (LMWHs) have many advantages over UFH. These agents have a greater bioavailability, can be administered by subcutaneous injections once or twice a day, and have a longer duration of anticoagulant effect. There is a lower risk of osteoporosis and immune-mediated thrombocytopenia.¹⁵² A fixed dose of LMWH can be used and laboratory monitoring is not necessary except in clinical circumstances such as morbid obesity, low weight (<40 kg), pregnancy, and renal insufficiency.¹⁵³ Comparison trials between LMWH and UFH have demonstrated that LMWH is at least as effective and as safe as UFH, and there

are no significant differences in recurrent thromboembolic events, major bleeding, or mortality risk between the two types of heparin.¹⁵⁴ Caution must be used when administering LMWH in patients with renal insufficiency. LMWH is primarily cleared by the kidneys. Therefore, monitoring anti-Xa activity should be performed in patients with impaired renal function. If the creatinine clearance is less than 30 mL/minute, UFH should be used.¹⁵⁵

LMWH heparin has a significantly lower incidence of heparin-induced thrombocytopenia (HIT), yet HIT can still occur with exposure to LMWH. Thus, LMWH is not an anticoagulant substitute for the patient with HIT requiring VTE prophylaxis or thrombosis treatment.¹⁵⁶

LMWH can be administered safely in an outpatient setting. This has led to the development of programs in which clinically stable patients with PE are treated at home, at substantial cost savings.¹⁵⁷ An international, open-label, randomized trial compared outpatient and inpatient treatment (both using the LMWH enoxaparin as initial therapy) of low-risk patients with acute PE and concluded that outpatient treatment was not inferior to inpatient treatment.¹⁵⁸

FONDAPARINUX

Fondaparinux is a synthetic polysaccharide derived from the antithrombin binding region of heparin. Fondaparinux catalyzes factor Xa inactivation by antithrombin without inhibiting thrombin, and studies have shown that it is effective in the initial treatment and prophylaxis of the VTE. Fondaparinux has been shown to be just as effective and safe as UFH and enoxaparin.¹⁵⁹ Fondaparinux dosing is based upon various weight ranges. For patients weighing less than 50 kg, 5 mg once daily is recommended. Patients weighing 50 to 100 kg are given 7.5 mg, and those weighing greater than 100 kg receive 10 mg daily. HIT is rare with the use of fondaparinux because of this lack of interaction with platelet factor 4 (PF4).¹⁴⁸

WARFARIN THERAPY

The anticoagulant effect of warfarin (Coumadin) is mediated by the inhibition of vitamin K–dependent factors, which are II, VII, IX, and X. Vitamin K antagonists (VKAs) include substances with a short (acenocoumarol), intermediate (warfarin, fluindione), or long (phenprocoumon) half-life. For this reason, and because of genetically induced metabolic variability, the variable vitamin K content of food, a narrow therapeutic index, and interactions with other drugs, the effect on coagulation must be closely monitored. The peak effect does not occur until 36 to 72 hours after drug administration and the dosage is difficult to titrate. Administration of heparins or fondaparinux should overlap during at least 5 days with that of VKAs. After 5 days the parenteral drug can be stopped when the anticoagulant concentration induced by the VKA has achieved international normalized ratio (INR) between 2.0 and 3.0.^{148,160}

The current American College of Chest Physicians (ACCP) guidelines for warfarin therapy suggest that the target INR is 2.5 even in high-risk patients (e.g., antiphospholipid syndrome). Because of its lack of validation, the ACCP does recommend pharmacogenetic testing. Warfarin should be started on day 1 or 2 that heparin is started. Usually warfarin 10 mg is administered and INR is adjusted

to target INR. There is an increased risk of bleeding when antiplatelet drugs (acetylsalicylic acid, clopidogrel) are administered along with warfarin. In patients with acute coronary syndrome, mechanical valves, or recent coronary artery bypass or coronary stents, there is a likely benefit from the combination. Nonsteroidal anti-inflammatory drugs (NSAIDs) also increase the risk of bleeding when taken with warfarin and should be avoided.¹⁶⁰

NEW ORAL ANTICOAGULANTS

A new generation of anticoagulants is emerging with promising advantages over current therapy. These drugs have their effect on specific steps of the coagulation cascade. These agents are taken orally and do not require hematologic monitoring. The direct thrombin inhibitor dabigatran and factor Xa inhibitors rivaroxaban, apixaban, and edoxaban are moving through the pipeline for Food and Drug Administration (FDA) drug approval. Rivaroxaban recently received U.S. FDA approval to expanded use of Xarelto (rivaroxaban) to include treating DVT or PE and to reduce the risk of recurrent DVT and PE following initial treatment. Two studies have demonstrated that rivaroxaban is as effective as warfarin.^{15,161} A major drawback, there is no reversal agent or antidote for hemorrhage induced by rivaroxaban.¹⁶²

DURATION OF ANTICOAGULATION THERAPY

A patient with a first thromboembolic event occurring in the setting of reversible risk factors, such as immobilization, surgery, or trauma, should receive warfarin therapy for at least 3 months. No difference in the rate of recurrence was observed in either of two studies comparing 3 versus 6 months of anticoagulant therapy in patients with unprovoked first events.^{69,70} The current recommendation is anticoagulation for at least 3 months in these patients; the need for extending the duration of anticoagulation should be reevaluated at that time.¹⁶³

The current ACCP guidelines recommend that all patients with unprovoked PE should undergo a risk-to-benefit evaluation to determine if long-term therapy is needed (grade 1C).¹⁶³ Long-term treatment is recommended for these patients who do not have risk factors for bleeding and in whom accurate anticoagulant monitoring is possible (grade 1A). Patients who have PE and preexisting irreversible risk factors, such as deficiency of antithrombin III, protein S and C, factor V Leiden mutation, or the presence of antiphospholipid antibodies, should be placed on long-term anticoagulation.

HEPARIN-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is common in the ICU setting but rarely is it caused by HIT. Because heparin is a common drug used in the ICU setting, this entity frequently is included in the differential diagnosis of the thrombocytopenia. The downstream consequences of overdiagnosis can be problematic, especially if it produced breaches in treating patients with VTE or protecting them from VTE.

HIT is a transient prothrombotic disorder initiated by heparin. The main features of HIT are (1) thrombocytopenia resulting from immunoglobulin G–mediated platelet activation and (2) in vivo thrombin generation and increased risk of venous and arterial thrombosis.¹⁶⁴

HIT may manifest clinically as an extension of the thrombus or formation of new arterial thrombosis. HIT should be suspected whenever the patient's platelet count falls to less than 100,000/ μ L or less than 50% of the baseline value, generally after 5 to 15 days of heparin therapy. The pretest probability for HIT can be determined by the application of the "4 Ts": (1) Thrombocytopenia, (2) Timing, (3) Thrombosis, and (4) no oTher explanation of thrombocytopenia. At low scores the probability of the presence of platelet-activating HIT antibodies is low; at high scores there is a moderate probability of the presence of the antibodies.^{164,165}

The diagnosis of HIT is based upon assays that detect the presence of platelet-activating antibodies. The PF4-dependent enzyme immunoassay (EIA) test may lead to overdiagnosis of HIT. However, a negative EIA essentially rules out HIT. The serotonin release assay (SRA) is more specific for HIT than the PF4-dependent EIA. EIA is measured in optical density units (OD) and the strength of this measurement is a strong predictor of a positive SRA and confirmed HIT. In a patient with thrombocytopenia in whom the OD of EIA was less than 1.5 units the thrombocytopenia was not caused by HIT.^{164,165}

The treatment of patients who develop HIT is to stop all heparin products, including catheter flushes and heparin-coated catheters, and to initiate an alternative, nonheparin anticoagulant, even when thrombosis is not clinically apparent. Preferred agents include direct thrombin inhibitors, such as lepirudin or argatroban. Start warfarin while the patient receives an alternative, nonheparin anticoagulant and only when the platelet count has recovered to at least 100,000/ μ L (preferably to 150,000/ μ L).¹⁴⁸

THROMBOLYTIC THERAPY

The goal of thrombolytic therapy, by accelerating the conversion of plasminogen to plasmin, is to promote clot lysis and unload the right ventricle by decreasing pulmonary vascular obstruction. Thrombolysis has demonstrated a more rapid resolution of pulmonary vascular obstruction with improvement of RV hemodynamics within 2 hours after initiation of infusion. However, the controversy regarding thrombolytic therapy is the unloading of the right ventricle associated with improved mortality rate. In the larger original thrombolysis trials, streptokinase and urokinase were compared with heparin alone at infusion rates of 24 and 12 hours, respectively. These studies demonstrated rapid reperfusion of the pulmonary vasculature, reduction in pulmonary resistance, and no difference in mortality rate when compared to heparin.^{166,167}

Currently three thrombolytics have FDA approval in the United States for acute PE: streptokinase, urokinase, and alteplase. Streptokinase and urokinase are nonselective agents activating both circulating and clot-bound plasminogen. Both agents have significant limitations; streptokinase is antigenic and may cause hypotension. Alteplase (tissue plasminogen activator [tPA]) is fibrin specific and is the thrombolytic of choice for the management of PE.^{168,169}

The current ACCP key recommendations for the use of thrombolytic therapy in acute PE are noted here:¹⁶³

1. In patients with acute PE associated with hypotension (e.g., systolic blood pressure <90 mm Hg) without a

high bleeding risk, we suggest systemically administered thrombolytic therapy (grade 2C—weak recommendation [suggestion]/low quality or very low quality evidence).

2. In most patients with acute PE not associated with hypotension, we recommend against systemically administered thrombolytic therapy (grade 1C—strong recommendation/low quality or very low quality evidence).
3. In selected patients with acute PE without hypotension and with a low bleeding risk in whom there appears to be a high risk of developing hypotension, we suggest administration of thrombolytic therapy (grade 2C—weak recommendation [suggestion]/low quality or very low quality evidence).
4. When a thrombolytic agent is used, we suggest short infusion times (e.g., a 2-hour infusion) (grade 2C—weak recommendation [suggestion]/low quality or very low quality evidence).
5. In patients with acute PE when a thrombolytic agent is used, we suggest administration through a peripheral vein. Central administration is not deemed necessary (grade 2C—weak recommendation [suggestion]/low quality or very low quality evidence). Incidence of major hemorrhage from systemic thrombolytic administration can be as high as 20%, including a 3% to 5% risk of hemorrhagic intracranial complications.

Currently, the thrombolytic that is recommended is tPA at a dose of 100 mg given intravenously over 2 hours. Once the tPA is started the UFH infusion is stopped. After the 2-hour infusion the heparin is restarted, without a loading dose, when the aPTT is less than 80 seconds after tPA is complete.

Contraindications to systemic thrombolytic therapy in acute PE include an intracranial neoplasm, recent (i.e., <2 months) intracranial surgery or trauma, active or recent internal bleeding during the prior 6 months, history of a hemorrhagic stroke, bleeding diathesis, severe uncontrolled hypertension (i.e., systolic blood pressure >200 mm Hg or diastolic blood pressure >110 mm Hg), nonhemorrhagic stroke within the prior 2 months, surgery within the previous 10 days, and thrombocytopenia (i.e., <100,000 platelets/mL). Thrombolytic therapy may cause moderate bleeding in menstruating women, but it has not been associated with major hemorrhage. Therefore, menstruation is not a contraindication to thrombolytic therapy.¹⁷⁰

SUBMASSIVE PULMONARY EMBOLISM WITH HEMODYNAMIC STABILITY AND RIGHT VENTRICULAR DYSFUNCTION

In patients with acute PE who are normotensive but demonstrate some degree of RVD, the treatment is somewhat controversial and may depend upon the degree of RVD present to initiate aggressive steps to protect RV function. There is a spectrum of RVD and RV injury. If RVD is manifested by only RV wall dilation and not injury, then the outcome may be different when injury begins to occur. The normotensive patients with evidence of RV injury will require expedited protection of RV function.

ROLE OF THROMBOLYTIC THERAPY IN NORMOTENSIVE SUBMASSIVE PULMONARY EMBOLISM WITH RIGHT VENTRICULAR DYSFUNCTION

Patients with known or suspected PE must be treated initially with UFH infusion. It appears that RVD in normotensive PE patients is associated with an increased risk of short-term adverse events and death than in patients without RVD. A number of studies have suggested that thrombolytic therapy should be considered in these patients. In the Management Strategy and Prognosis of Pulmonary Embolism Registry, of 719 acute PE patients with normal systemic arterial blood pressure and echocardiographic evidence of RVD, 550 were treated with heparin alone and 169 patients received thrombolytic therapy. The subgroup analysis demonstrated that patients undergoing thrombolysis had a significantly lower in-house mortality rate at 4.1% in contrast to anticoagulation alone at 10.5%. PE recurrence was observed in 7.7% in the thrombolysis group and in 18.7% in patients receiving anticoagulation alone.² Although this study demonstrated differences in terms of mortality rates and PE recurrence between the two groups, it must be emphasized that this was a registry trial and not a randomized clinical investigation. Therefore, it was subject to unavoidable selection bias.

An important study that attempted to determine whether normotensive patients with PE-induced RVD should receive thrombolytic therapy produced some very interesting conclusions. In a prospective trial (MAPPET-3 [Management Strategies and Prognosis of Pulmonary Embolism-3 Trial]) of 256 patients with PE, the investigators randomized patients to receive heparin plus either recombinant tissue plasminogen activator (rtPA) or placebo. This study used a combined end point of in-hospital death or clinical deterioration (escalation of therapy needed). Clinical deterioration was defined as a requirement for either a catecholamine infusion to treat hypotension or shock, secondary or “rescue” thrombolysis, endotracheal intubation, cardiopulmonary resuscitation, or emergency catheter or surgical embolectomy. Initially the study results seem to support the use of thrombolytic therapy. Patients treated with anticoagulation alone were more likely to die or require treatment escalation than those who received rtPA (24.6% vs. 11.0%; $p = 0.006$), and importantly, there was no difference in the incidence of major bleeding or intracranial hemorrhage between the two treatment groups. The difference between the two groups was due to a more frequent need for secondary emergency thrombolysis in the heparin group, although the overall mortality rate was not affected by thrombolysis.¹⁷¹ One of the major problems with this study was the lack of a consistent definition of RVD. In this study various modalities were used to define RVD and included echocardiography, right-sided heart catheterization, and even ECG signs of RV strain. Nevertheless, this study has been the catalyst for a large multinational European trial currently under way to attempt to resolve the controversy surrounding the role of thrombolytic therapy in patients with PE who are normotensive but have RVD.

Based upon the current ACCP guidelines, normotensive PE patients who have RVD (from clinical, biomarker, and echocardiographic findings) and no contraindications to thrombolysis, systemic thrombolysis should be considered (grade 2C recommendation).

ROLE OF CATHETER-DIRECTED THERAPY IN NORMOTENSIVE SUBMASSIVE PULMONARY EMBOLISM WITH RIGHT VENTRICULAR DYSFUNCTION

Catheter-directed therapy (CDT) has the potential to locally reduce clot burden in the pulmonary artery by mechanically disrupting the clot or locally infusing low-dose thrombolytics or both. In hemodynamically stable patients with RVD who have right and left pulmonary PE or main pulmonary artery clot CDT may be considered. However, CDT provides an additional option in the treatment of patients with life-threatening PE and a possible alternative to surgical embolectomy and systemic thrombolysis, especially in patients who are poor surgical candidates and have relative contraindications to systemic thrombolysis. Bleeding risk appears to be lower in CDT administered thrombolysis compared to systemic thrombolysis.¹⁷²

The three types of catheter-based interventions are (1) aspiration thrombectomy, (2) thrombus fragmentation, and (3) rheolytic thrombectomy. Each of these techniques has similar success rates in systematic reviews.¹⁷²

The infusion of tPA can be accomplished unilaterally or bilaterally at a total dose rate of 1.0 to 2.0 mg/hour depending on the degree of clot burden. In patients who may be at greater risk for bleeding or may require prolonged infusions greater than 24 hours, fibrinogen levels should be monitored. When the fibrinogen level is decreased below 150 to 200 mg/dL the infusion should be reduced or discontinued.¹⁷² The ACCP currently recommends that CDT be considered in selected highly compromised patients with PE who are unable to receive thrombolytic therapy because of bleeding risk. The decision to consider CDT therapy should be multidisciplinary in nature. Case-by-case assessment is based upon risk stratification findings and the patient's risk of systemic thrombolysis and status as a candidate for surgical management.

ROLE OF INFERIOR VENA CAVA FILTERS IN PATIENTS WITH SUBMASSIVE PULMONARY EMBOLISM WITH RIGHT VENTRICULAR DYSFUNCTION

The goal of the inferior vena cava (IVC) filter intervention is to prevent further potentially lethal embolic episodes from impacting on an already compromised right ventricle. The current IVC filters that are utilized are retrievable and usually placed by interventional radiology. There has been a marked increase in the use of IVC filters for treatment and prevention of the venous thromboembolic disease. Stein and colleagues showed that the use of IVC filters in the United States has increased from 2000 in 1979 to 92,000 in 2006.¹⁷⁴

IVC filters are usually placed in patients with acute PE or DVT who develop active bleeding during anticoagulation and an existing contraindication to anticoagulation. IVC filters should also be considered in the following situations: (1) recurrent thromboembolism despite adequate anticoagulation, (2) the presence of a large free-floating caval thrombus, (3) chronic recurrent PE with pulmonary hypertension, and (4) patients who have had surgical embolectomy or pulmonary endarterectomy.¹⁷⁵

The Greenfield filter was introduced in 1973, and subsequently many types of permanent IVC filters have been developed; these filters are usually placed under

There are no large prospective randomized CDT trials for making evidence-based recommendations. In a meta-analysis of 594 patients with acute massive PE treated with CDT, clinical success was achieved in 86.5%, with success defined as the stabilization of hemodynamics, resolution of hypoxia, and survival to hospital discharge.¹⁷³ In the same study, 96% of patients received CDT as the first adjunct to heparin with no previous systemic tPA infusion, and 33% of cases were initiated with mechanical treatment alone without local thrombolytic infusion. When injected locally, the required dose of tPA is likely to be lower compared with a full-dose systemic tPA infusion, and there is less risk for bleeding. Indeed, the rate of major complications from modern CDT has proved to be only 2.4%.

The goal of all these techniques is rapid central clot debulking to relieve life-threatening heart strain and immediately improve pulmonary perfusion. Catheter intervention is important not only for creating an immediate flow channel through the obstruction but also for exposing a greater surface area of thrombus to the effects of locally infused thrombolytic drug. In patients with overt shock, thrombus fragmentation is usually the first priority of therapy with the goal to expedite reduction in clot burden.

(Acute PE with SBP >90 mm Hg with RV Dysfunction)

fluoroscopic guidance.¹⁷⁶ Retrievable IVC filters offer an attractive alternative to the standard permanent filters. These retrievable filters are inserted in patients who may have transient contraindications to anticoagulation or patients who have increased bleeding risks (e.g., trauma patients and neurosurgical patients) or in whom the RV hemodynamics normalize. These filters should be removed within 3 months after implantation; unfortunately, these filters are not removed in “real world” practice.¹⁷⁵

In patients with submassive PE and RVD who are normotensive the role of the retrievable IVC filter to prevent further embolization is controversial. In a small retrospective study adjunctive placement of an IVC filter, especially in patients with RV strain, resulted in no deaths. In patients who did not receive a filter the in-house mortality rate was 10.2%.¹⁷⁹ Prospective studies are needed to further explore the role of retrievable IVC filters in this patient population.

Figure 44.7 illustrates the therapeutic options available for the management of submassive PE in normotensive patients with RVD. In summary, the goals of these interventions are to reduce clot burden and to prevent further embolic impact on a compromised right ventricle.

MASSIVE PULMONARY EMBOLISM

RESPIRATORY SUPPORT

Although mechanical ventilation is often required in massive PE, the hemodynamic effects of mechanical ventilation may further aggravate the vicious circle of RVD and ischemia by augmenting RV afterload and further decreasing LV preload. Limiting the vasodilating hemodynamic effects of sedation and anesthesia needed for intubation is important.

Intubating a patient with massive PE should not be prophylactic, and the risk versus benefit must be weighed carefully for each patient.¹⁸⁰

HEMODYNAMIC SUPPORT IN MASSIVE PULMONARY EMBOLISM

Volume Resuscitation

Fluid should be administered in massive PE with caution. Fluid resuscitation may increase RV afterload precipitating RV failure as well as augment septal ballooning into the left ventricle, further decreasing cardiac output and worsening systemic hypotension. It is therefore recommended that small boluses of fluid (250-500 mL aliquots) be used initially to evaluate affect.^{181,182}

Vasoactive Drugs

There are no randomized controlled studies among different vasoactive agents in massive PE. Norepinephrine (NE) which has both α -adrenergic and β -adrenergic effects, is superior to phenylephrine in a canine model of PE in terms of both improving cardiac output and improving myocardial perfusion.¹⁸³ NE has been shown to increase cardiac contractility and RV perfusion pressure, thus increasing coronary blood flow. Therefore, NE has become the most frequently used vasoactive agent for hemodynamic support of massive PE.^{183,184} Dopamine, which possesses both β -adrenergic and, at sufficiently high doses, α -adrenergic agonist effects, appears to offer similar benefit. However, its use may be limited by the development of tachycardia.¹⁸⁵

Inotropic Agents

Dobutamine, in combination with NE in the hypotensive patient, should be considered first-line therapy when

The 1998 PREPIC study and its 8-year follow-up suggested that IVC filters reduce the risk of PE, while increasing the risk of recurrent DVT, and do not reduce the all-cause mortality rate.¹⁷⁷ Four hundred patients with proximal DVT were randomized to receive IVC filter or no IVC filter and all had received enoxaparin or UFH as a bridge to warfarin therapy, which was continued for at least 3 months. The primary end points were recurrent DVT, PE, major bleeding, and death. The patients were followed up at day 12, at 2 years, and then annually up to 8 years following randomization. At day 12, there were fewer PEs in the group that received filters (OR 0.22, 95% CI, 0.05-0.90). However, at year 2, there was no significant difference in PE development in the filter group compared with the no-filter group (OR 0.50, 95% CI, 0.19-1.33). Additionally, at year 2, the

filter group was more likely to develop recurrent DVT (OR 1.87, 95% CI, 1.10-3.20). At year 8, there was a significant reduction in the number of PEs in the filter group versus the no-filter group (6.2% vs. 15.1%, $p = 0.008$). However, at 8-year follow-up, IVC filter use was associated with increased DVT (35.7% vs. 27.5%, $p = 0.042$). There was no difference in mortality rate between the two groups. In summary, the use of IVC filters was associated with decreased incidence of PE at 8 years, offset by higher rates of recurrent DVT and no overall mortality benefit.^{177,178} Importantly, the indications for IVC filter use in this study differ from the current ACCP guidelines; all patients were given concomitant anticoagulation for at least 3 months, which might not be possible in patients for whom the ACCP recommends IVC filters.

treating cardiogenic shock secondary to a massive PE. In 10 patients with massive PE, dobutamine was able to increase cardiac index while reducing right atrial pressure, systemic vascular resistance, and PVR.¹⁸⁶ Although phosphodiesterase inhibitors have been used to support the circulation in cardiogenic shock secondary to massive PE, these agents should be used with caution given the lack of literature support. Their significant vasodilating capabilities could potentially worsen hypoxemia due to their ameliorating effect on hypoxic vasoconstriction and potentially worsen systemic hypotension.¹⁸⁷

SYSTEMIC THROMBOLYSIS IN MASSIVE PULMONARY EMBOLISM

If there are no contraindications, thrombolytic therapy is the treatment of choice for massive PE resulting in severe hemodynamic and respiratory compromise. This recommendation is sanctioned by the current ACCP guidelines.¹⁶³ A number of studies have demonstrated the superiority of thrombolytic therapy in improving RV function (24-48 hours) when compared with heparin alone. The studies have not demonstrated an improvement in mortality rate with thrombolysis.^{166,167,188-190} One reason is that the studies were not large enough for mortality rate to be an outcome measurement. A meta-analysis by Wan and colleagues demonstrated that patients with massive PE had a reduction in mortality rate and PE recurrence and adverse events when compared with heparin alone (19.0% to 9.4%; OR, 0.45; 95% CI, 0.22-0.92).¹⁹¹ If thrombolytic therapy is given within 48 hours of the pulmonary embolic event there may be greater clinical improvement. However, thrombolysis may continue to be beneficial even in patients who have symptoms up to 2 weeks out from their initial PE symptoms.¹⁹²

The thrombolytic agent usually given is tPA in a 2-hour infusion via peripheral venous line. UFH should not be given at the time with thrombolytic therapy. UFH should be restarted after the thrombolytic infusion is completed and when the aPTT is less than twice the normal value.

Massive PE can lead to cardiac arrest and the initial rhythm may include PEA and asystole. When cardiac arrest occurs, the mortality rate is in the range of 66% to 95%. Thrombolytic therapy given in boluses of 50 mg has been shown in case reports to be lifesaving.¹⁹³

INFERIOR VENA CAVA FILTERS IN MASSIVE PULMONARY EMBOLISM

An observational study from an international registry that suggests that IVC filter placement in patients with massive PE (i.e., with hypotension) was associated with a reduction in combined end point of mortality rate and recurrent PE. This study cohort was small; however, it appears to be reasonable that IVC filters should be placed in patients with poor cardiopulmonary reserve.¹⁹⁴

Unstable PE patients who are treated with standard anticoagulation therapy may benefit further with prophylactic placement of IVC filters. In a recent study by Stein and associates,¹⁹⁵ the mortality rate in 38,000 unstable patients treated with standard anticoagulant therapy alone was 51% compared with 33% in 12,850 who had vena cava filters in addition to anticoagulants. This represents a 35% decrease in the case fatality rate when vena cava filters are combined with standard anticoagulant therapy.

PULMONARY EMBOLIC THERAPY IN MASSIVE PULMONARY EMBOLISM

The indications for pulmonary embolectomy are patients with documented massive PE confirmed if possible by angiography (CTPA or pulmonary angiography) with persistent hemodynamic instability despite aggressive medical therapy including consideration of the local or systemic thrombolysis. Patients with refractory shock in which massive PE is strongly suspected should be transferred to a center where emergent surgical management for PE is performed. These patients must be urgently transferred to the operating room and on the operating table TEE should be performed to confirm the diagnosis. Despite these efforts, patients who present with cardiac arrest have a high surgical mortality rate.^{195,196}

The mortality rate from pulmonary embolectomy ranges from 30% to 40%. There has been concern that medical therapy may delay definitive surgical therapy and may account for the high mortality rate. Among 1047 patients who underwent pulmonary embolectomy from 1961 to 1984 the average in-house mortality rate was 32%. Using the National Inpatient sample from 1999 to 2008, recently Stein and colleagues showed that the case fatality rates for unstable patients (shock or ventilator-dependent) with PE undergoing pulmonary embolectomy was 40% and in stable patients 24% with an overall case fatality rate of 28%. The case fatality rates were lower in patients with the primary diagnosis of PE who had few comorbid conditions. It was observed in both groups that patients with IVC filters had a lower case fatality rate than those who did not have filters.^{197,198} More recently the surgical mortality rates for pulmonary embolectomy have decreased at specialized centers (Fig. 44.8, pulmonary embolectomy). A multidisciplinary approach appears to be the key to diagnosis, treatment, and postoperative care, translating to reduced mortality and morbidity rates.^{199,200}

ENDOVASCULAR THERAPY IN MASSIVE PULMONARY EMBOLISM

In patients with massive PE who are not candidates for either pulmonary embolectomy or systemic thrombolysis, if there is institutional expertise for endovascular management, this should be considered. The goal is to convert a massive PE into a submassive PE with resultant improvement in the patient's hemodynamic and respiratory status. Initially CDT provides mechanical debulking of the clot, and if indicated because of persistent elevation of pulmonary artery pressures, infuse low-dose (3 mg/hour) tPA directly into the clot over a 12- to 24-hour period. CDT should be considered and the decision should be made quickly as part of a multidisciplinary discussion.¹⁷²⁻²⁰³ Complications of CDT are rare, but when they occur they can be serious. They include perforation of the pulmonary artery or perforation of the atrium or ventricle with pericardial tamponade. These interventions should be performed only by clinicians who are experienced in catheter-based intervention and within institutions that have defined protocols and multidisciplinary teams to manage these critically ill patients.

The management of high-risk submassive PE is summarized in Figure 44.9. For the normotensive patient with PE it is important to quickly risk stratify and identify the patient with RVD and large clot burden. If patients in this subset

Figure 44.8 Large clot burden removed by pulmonary embolectomy.

manifest signs of RV injury with persistent elevations in troponin and echocardiographic evidence of RV overloading with impending RV failure, then systemic thrombolytic therapy, local thrombolytic therapy, and surgical management are management options to be considered. In the patient with massive PE, as with submassive PE with RVD, there must be multidisciplinary coordination between interventional cardiology and radiology and cardiothoracic surgery to quickly determine the best treatment approach. Both respiratory and hemodynamic support will allow some time to consider the various management options.

SPECIAL POPULATIONS

PREGNANCY

The incidence of PE during pregnancy ranges between 0.3 and 1 per 1000 deliveries.²⁰⁴ PE is the leading cause of pregnancy-related maternal death in developed countries. In the United States, maternal death from PE ranks third after hemorrhage and hypertensive disorders.^{105,206} There is a fivefold increased risk of VTE in the pregnant woman because of venous stasis, a prothrombotic state as a result of increased levels of coagulation factors, reduced protein S, and fibrinolytic activity.²⁰⁷ The two major PE risk factors in pregnancy are a personal history of VTE and heritable thrombophilias.²⁰⁸ The risk of PE is higher in the postpartum period, particularly after a cesarean section. The clinical features of PE are no different in pregnancy compared with the nonpregnant state. There have been no prospective trials that have validated existing prediction models to

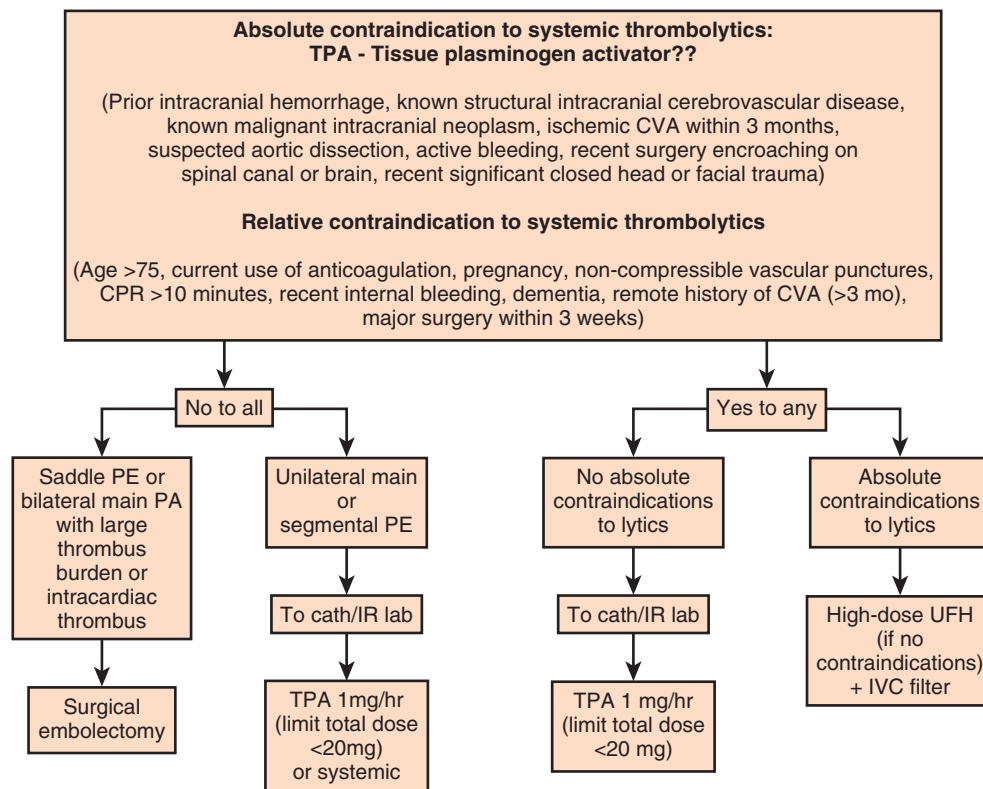

Figure 44.9 “High-risk” submassive pulmonary embolus with right ventricular injury algorithm.

exclude PE in pregnancy. It has been shown from a maternal death review that pregnant women who died from PE are over the age of 35, are obese (body mass index >30), and have chronic medical conditions.²⁰⁹

DIAGNOSIS OF PULMONARY EMBOLISM IN PREGNANCY

Although D-dimer may be elevated in pregnancy, leading to a high rate of false positives, a normal D-dimer value has the same exclusion value for PE in pregnant women as in other patients with suspected PE. However, it has been suggested that D-dimer testing is not recommended for evaluation of suspected VTE in pregnancy or the early postpartum period. Therefore, it should be measured even though the probability of a negative result is lower than in other patients with suspected PE.²⁰⁷

An elevated D-dimer assay should be followed by CUS of the lower extremities. If CUS demonstrates DVT, then anticoagulation can occur and thoracic imaging is not necessary. If CUS is negative and the diagnosis is still suspected, then thoracic imaging is warranted. It is important to note that the upper limit of radiation with regard to the danger of injury to the fetus is considered to be 50 mSv (50,000 mGy), and all radiologic tests (CT and \dot{V}/\dot{Q}) fall well below this limit.²⁰⁸ In a pregnant or postpartum woman suspected of PE with a normal chest radiograph either a ventilation-perfusion scan or a perfusion scan alone will be sufficient. A normal lung scan essentially excludes the diagnosis of PE. Perfusion scanning compares favorably with CT as far as exposure of breast tissue to radiation is concerned.²⁰⁹ If the chest radiograph is abnormal and the lung scan is nondiagnostic, then CTPA is recommended.

TREATMENT OF PULMONARY EMBOLISM IN PREGNANCY

The medical treatment of PE in pregnancy is heparin—either UFH or LMWH, neither of which crosses the placenta or is found in breast milk in any significant amount. As there are no specific data in the setting of pregnancy, treatment should consist of a weight-adjusted dose of LMWH. Adaptation according to anti-Xa monitoring may be considered in women at extremes of body weight or with renal disease. The heparin treatment should be given throughout the entire pregnancy. From limited data fondaparinux appears efficacious in pregnancy, but bleeding risk is not absent, and care is required when used as second-line therapy.²¹⁰

The new oral anticoagulants are not to be used during pregnancy. Teratogenic effects, reduced fetal viability, hemorrhagic changes, and placental abnormalities have been found in both dabigatran and rivaroxaban. Rivaroxaban is secreted in breast milk.²¹⁰ VKAs cross the placenta and are associated with a well-defined embryopathy during the first trimester. Administration of VKAs in the third trimester can result in fetal and neonatal hemorrhage as well as in placental abruption. Warfarin may be associated with central nervous system anomalies in any trimester in pregnancy.²⁰⁸

The management of labor and delivery requires particular attention. Epidural analgesia cannot be used unless LMWH is discontinued at least 12 hours before an epidural approach. Treatment can be resumed 12 to 24 hours after withdrawal of the epidural catheter. In any case, close collaboration among obstetrician, anesthetist, and critical care

physician is recommended. After delivery, heparin treatment may be replaced by anticoagulation with VKA. Anticoagulant treatment should be administered for at least 3 months after delivery. VKAs can be given even to breastfeeding mothers.²⁰⁸ Thrombolytic therapy should be used when there is a life-threatening pulmonary embolic event. At the time of delivery, thrombolytic treatment should not be used except in extremely severe cases and if surgical embolectomy is not immediately available. Indications for IVC filters in pregnant women are similar to those in other patients with PE.

In summary, in pregnant women with a clinical suspicion of PE an accurate diagnosis is paramount, as a prolonged course of heparin is required. All diagnostic modalities, including CT scanning, may be used without significant risk to the fetus. LMWHs are recommended in confirmed PE; VKAs are not recommended during the first and third trimesters but could be considered with caution in the second trimester of pregnancy. Anticoagulant treatment should be administered for at least 3 months after delivery.²⁰⁸

RIGHT-SIDED HEART THROMBI

Echocardiographically documented right-sided heart thrombi occur in approximately 4% of patients with PE.^{25,143} These patients have more hemodynamic instability and have a higher mortality rate. In the ICOPER study in patient with acute PE and a free-floating right-sided heart thrombus, the mortality rate was 15% compared to 11% without such thrombi.¹⁴³

In these patients, the treatment of choice is controversial. Thrombolytic therapy or surgical embolectomy have both been used and there have been multiple reports of successful results. In the ICOPER, thrombolytic treatment was the preferred option, but the 14-day mortality rate was above 20%.¹⁴³ In contrast, excellent results with thrombolytic therapy were reported in a series of 16 patients, in which 50%, 75%, and 100% of clots disappeared from the right side of the heart within first 2, 12, and 24 hours after administration of thrombolytics. All patients survived 30 days.²¹¹ It appears from the literature that treatment with heparin alone is not a treatment option.

For right-sided heart thrombi crossing the interatrial septum (patent foramen ovale) surgical embolectomy is warranted (Fig. 44.10). Whichever therapy is selected, it should be implemented without delay: in the presence of unequivocal echocardiographic visualization of a mobile right-sided heart thrombus, no further diagnostic tests are needed.^{25,203,212,213}

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Chronic thromboembolic pulmonary hypertension (CTEPH) is an uncommon but serious sequela of PE.

PROPHYLAXIS

The VTE event is a common and recognized complication in critically ill patients. A VTE event can have dire consequences on the critically ill patient with preexisting

CTEPH is an uncommon but serious sequela of PE. Certain patients with PE develop an aberrant and incomplete resolution of the thrombotic event, resulting in endothelialized thrombi and if left unchecked will result in the development of a distal, small vessel vasculopathy. This event results in progressive increases in RV afterload and pulmonary hypertension. When small distal vessel disease develops in patients with CTEPH the patient no longer is a candidate for surgical management.²¹⁴ The reasons are unclear for this divergent pathway in thrombus resolution. Acquired and hereditary risk factors are suspected. For example, 20% of CTEPH patients have antiphospholipid syndrome and increased levels of factor VIII are found in CTEPH when compared with nonthrombotic pulmonary hypertension and control groups.^{203,212,213} Characteristics of the initial acute embolic event may be associated with subsequent development of CTEPH. Persistent RVD at discharge and persistent elevation of pulmonary artery pressures may play a role.^{214,215}

In the past it was estimated that the incidence of CTEPH was only 0.1% to 0.5%.²¹⁴ Recent prospective studies have shown that CTEPH is much more common, with an incidence ranging from 1% to 3.8% of patients who survived their acute pulmonary embolic event. It is estimated that in the United States 6000 to 22,000 new cases potentially may occur in each year.^{214,216-218}

The \dot{V}/\dot{Q} lung scan plays a central role in the evaluation of patients with pulmonary hypertension. The \dot{V}/\dot{Q} scan in a patient suspected with CTEPH will show the “mottled” appearance of subsegmental and segmental perfusion defects. Larger defects can also be seen.²¹⁴ The lung scan is superior to CT angiography in screening patients for CTEPH. In a single center retrospective investigation comparing the lung scan with CT angiography and 227 patients with pulmonary hypertension demonstrated a sensitivity of 97.4% for \dot{V}/\dot{Q} scanning but only 51% for CT angiography in detecting chronic thromboembolic disease.²¹⁹

CT or MRA can be used to plan surgical intervention. Right-sided heart catheterization is required to determine the degree of hemodynamic impairment, and conventional pulmonary angiography can determine the proximal location of the thrombotic obstruction.²¹⁴

Surgical removal of the obstructing material requires a true endarterectomy as opposed to a simple embolectomy. The current approach to pulmonary endarterectomy requires median sternotomy, cardiopulmonary bypass, and periods of hypothermic circulatory arrest in order to provide adequate visibility. The main pulmonary arteries are incised and the right endarterectomy level within the wall is defined. Thereafter, the plane is followed circumferentially down to the segmental and sometimes subsegmental branches of each lobar artery, a procedure that is performed with the help of special suction dissectors.^{217,218}

The perioperative mortality rate is related to the severity of the disease, with a mortality rate of 4% in patients with a preoperative PVR less than 900 dynes/second/cm⁻⁵ and 20% in those with PVR above 1200 dynes/second/cm⁻⁵. The functional results of a successful pulmonary thromboendarterectomy are excellent and generally are sustained over time, with a 3-year survival rate of about 80%.²¹⁹⁻²²¹

The major causes of postoperative fatality from pulmonary endarterectomy are RV failure related to persistent pulmonary hypertension and acute lung injury. Lifelong anticoagulation and placement of the IVC filter are recommended. In patients who are deemed inoperable because of distal chronic thromboembolic disease or in whom the surgical mortality risk of endarterectomy is high, medical therapy that is developed for idiopathic pulmonary arterial hypertension has been studied in patients with CTEPH. It is important to identify patients as early as possible so they may have the opportunity for pulmonary endarterectomy because the hemodynamic and symptomatic benefits that medical therapy provide are modest.^{214,222,223}

Figure 44.10 Embolism in transit through the patent foramen ovale and surgical removal. (Courtesy of Dr. Omar Lattouf—Emory University Cardiothoracic Surgery.)

cardiopulmonary compromise. All critically ill patients have significant risk factors for VTE and also are at higher risk for bleeding. Venous thromboembolic prophylaxis decreases the risk of VTE in ICU patients.¹⁷⁻²¹ DVT prophylaxis is effective at reducing the risk of death. In several meta-analyses of surgical patients, prophylactic measures reduced the development of thromboembolic events by more than 50% and also the VTE-attributable mortality rate.²²⁴

Lack of adherence to evidence based VTE prophylaxis guidelines has been problematic on a national and international scale.^{13,224} With the implementation of electronic medical admission order sets universal VTE prophylaxis can be achieved. Extended posthospitalization prophylaxis has been recommended in orthopedic surgical and medical patients. The advent of safe and effective prophylaxis strategies makes all critical care patients candidates for some form of preventive therapy on the basis of risk factors present in this population of patients. Several studies suggest that more than 85% of hospitalized patients are receiving some sort of DVT prophylaxis. VTE prophylactic measures are

growing in ICUs with quality care initiatives targeting this intervention via bundled care pathways.^{225,226}

The administration of prophylactic LMWH (or low-dose unfractionated heparin) can be administered to the majority of critically ill patients. Critically ill patients at high risk for clinically important bleeding should receive mechanical thromboprophylaxis until the bleeding risk decreases. Renal insufficiency is not a contraindication to the use of LMWH or low-dose unfractionated heparin.

LONG-TERM PROGNOSIS

Nearly 25% of patients with PE do not survive the first year after the diagnosis. A majority of these patients succumb to underlying conditions, such as cancer or chronic heart disease, rather than PE. After surviving the first year the patient continues facing bleeding complications from anti-coagulation therapy, the risk of recurrent VTE, the development of cancer, and the development of CTEPH.²²⁷

KEY POINTS

- DVT and PE are different manifestations of the same disease and are associated with significant morbidity and mortality rates. The U.S. Surgeon General issued a “Call to Action” in 2008, identifying VTE as a major public health problem.
- It is important to identify patient-related and setting (ICU)-related risk factors for the development of VTE. ICU risk factors that are associated with massive PE are malignancy, cardiopulmonary disorders, and immobilization.
- Nearly two thirds of patients who die from pulmonary thromboembolism die within 1 hour of presentation, giving rise to the concept of the “golden hour” to accomplish both diagnosis and commence treatment. The principal pathophysiologic effects of pulmonary thromboembolism result from the impaction of clot in the pulmonary circulation with resulting vascular obstruction and humoral mediator release.
- Life-threatening PE, ranging from signs and symptoms of RVD to frank shock, are the major clinical presentations to the ICU.
- Risk stratification is useful in the assessment of submassive normotensive PE with RVD. RVD can be identified from clinical findings, ECG, cardiac biomarkers, and imaging modalities (echocardiogram and CTPA). The initial hemodynamic presentation of PE is the most powerful predictor of outcome. Central location of a thrombus is an independent risk factor for death.
- The cornerstone of pharmacologic management of VTE is heparin. Heparin therapy should be initiated, if there is no contraindication, as the diagnostic evaluation is being performed. UFH, LMWH, or fondaparinux followed by warfarin is currently the standard treatment for low-risk PE. New oral agents have been recently approved. Thrombolytic therapy, if

Continued on following page

Long-term prognosis may depend on whether the pulmonary embolic event was provoked or unprovoked (occurring in the absence of known risk factors). The prognosis of unprovoked PE may be more unfavorable than that for patients who experience provoked PE. Studies have shown that patients with provoked PE when compared with their unprovoked counterparts are at higher risk for recurrent PE, arterial cardiovascular events, the occurrence of cancer, and CTEPH.²²⁸⁻²³²

In a recent study Klok and colleagues investigated the long-term prognosis of acute PE in 308 unprovoked patients, 558 patients with provoked PE, and 334 patients without PE for a median follow-up period of 3.3 years. The mortality rate for the acute embolic event was 5.2%. The adjusted HR for recurrent VTE was increased for patients with unprovoked versus provoked PE (HR 2.1; 95% CI, 1.3-3.1) and unprovoked versus patients without PE (HR 10; 95% CI, 4.9-28). Recurrent PE was fatal in 19% of the patients and these fatalities usually occurred after 3 weeks from the initial PE episode. The risk for cancer was higher for the patients

after unprovoked PE than for the patients with provoked (adjusted HR 4.4; 95% CI, 2.0-10) and without PE (adjusted HR 2.5; 95% CI, 1.1-2). Patients with unprovoked PE suffered severe cardiovascular disease two to three times more often than the patients from the other two study cohorts (adjusted HR 2.6; 95% CI, 1.5-3.8; and HR 2.4; 95% CI, 1.2-3.7). There was no difference in the pooled risk for adverse outcome of patients with unprovoked and provoked PE, although the risk on all separate end points except for malignancy-related death was markedly higher for the patients with unprovoked PE. From this study, in nearly 4 years after the embolic event, half of the patients diagnosed with acute PE died or were diagnosed with cancer, recurrent VTE, CTEPH, or arterial cardiovascular disease. This study sets forth a clarion call for studies to develop and evaluate accurate prediction strategies for duration of treatment and to provide further insight on clinical surveillance and personal prognostication for the patients who have survived their initial embolic event.²³³

KEY POINTS (Continued)

- there are no contraindications, should be used in patients with massive PE and considered in patients with submassive PE with evidence of severe RVD.
- The management of the normotensive submassive PE patient centers on reducing RV afterload and preventing further insult to the right ventricle. Systemic and endovascular delivery of thrombolytic agents can reduce RV strain. The placement of a retrievable IVC filter can prevent further embolic impact on the RV.
 - Supportive therapy for massive PE employs judicious use of fluids to avoid further increases in RV strain. NE is the vasopressor of choice to maintain perfusion pressure. Dobutamine should be used to improve contractility. These temporizing measures will allow the critical care team to mobilize thrombolytic, endovascular, and surgical management strategies. All diagnostic modalities, including CT scanning, may be used without significant risk to the fetus in the pregnant woman. LMWHs are recommended in confirmed PE. Anticoagulant treatment should be administered for at least 3 months after delivery.
 - Thrombolytic therapy or surgical intervention should be considered for right-sided heart thrombi. If a patent foramen ovale is present or right-sided heart thrombi cross the patent foramen ovale, surgery should be performed.
 - CTEPH is more common than once thought and is best managed with pulmonary endarterectomy. It is important to identify these patients early.
 - VTE prophylaxis strategies are necessary for nearly all critical care patients.
 - Four years after PE the majority of patients will have either died or had recurrent PE, cancer diagnosis, arterial cardiovascular disease, or CTEPH. We must do more in following up these post-PE patients.

PROGNOSIS

Pulmonary hypertension (PH) is a complex and heterogeneous pulmonary vascular disorder that leads to elevated pulmonary vascular resistance (PVR) and right ventricular failure. During recent years, multiple advances in the therapy and management of PH have been made; however, this disorder continues to cause significant morbidity and mortality. PH is defined by a resting mean pulmonary arterial pressure (mPAP) greater than 25 mm Hg, associated with PVR greater than $240 \text{ dynes} \cdot \text{second} \cdot \text{cm}^{-5}$ (or >3 Wood units) measured by right-sided heart catheterization. It is very important for the intensivist to distinguish those patients who have chronic PH secondary to any of the five groups included in the clinical classification described in [Box 45.1](#) from other conditions that are usually faced in the intensive care unit (ICU) that can cause an acute elevation in the PVR. The acute elevation of pulmonary artery (PA) pressure observed in critically ill patients can develop on top of preexisting chronic PH (acute on chronic). It can be transient without consequences, or it can be prolonged and progress to severe acute PH, leading to life-threatening complications that include refractory systemic arterial hypotension, severe hypoxemia, right ventricular dysfunction and failure, and ultimately cardiogenic or obstructive shock and death. The most common acute elevation of PA pressures in the ICU is seen in the setting of left-sided heart disease (elevated pulmonary venous pressure) or in patients with preexisting pulmonary vascular disease. It is also well

recognized after cardiothoracic surgery, during sepsis, after pulmonary embolism (PE), and in acute respiratory distress syndrome (ARDS). Unfortunately, in most cases acute PH remains underdiagnosed and its treatment begins only after serious complications have been developed.

PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION AND RIGHT VENTRICULAR FAILURE

DEVELOPMENT OF PULMONARY HYPERTENSION

In order to understand the pathophysiology of PH and before reviewing its current clinical classification, it is important to identify where the vascular insult originates. Conditions that raise the postcapillary pressure (pulmonary venous pressures) such as left-sided heart failure or mitral stenosis differ significantly from conditions that primarily affect the pulmonary arteries and arterioles such as idiopathic pulmonary artery hypertension (IPAH). The former causes a gradient between the PA diastolic and pulmonary capillary wedge pressure (PCWP) that is relatively small, with histopathologic changes in the arterial vessels that consist of mild medial hypertrophy and reversible intimal changes. In the latter, there is an increased pulmonary arteriovenous pressure gradient, and histologic changes on the

Box 45.1 Clinical Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension (PAH)
 - 1.1. Idiopathic PAH
 - 1.2. Heritable
 - 1.2.1. BMPR2
 - 1.2.2. ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
 - 1.2.3. Unknown
 - 1.3. Drug- and toxin-induced
 - 1.4. Associated with:
 - 1.4.1. Connective tissue diseases
 - 1.4.2. HIV infection
 - 1.4.3. Portal hypertension
 - 1.4.4. Congenital heart diseases
 - 1.4.5. Schistosomiasis
 - 1.4.6. Chronic hemolytic anemia
 - 1.5. Persistent pulmonary hypertension of the newborn
 - 1'. Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (PCH).
2. Pulmonary hypertension owing to left heart disease
 - 2.1. Systolic dysfunction
 - 2.2. Diastolic dysfunction
 - 2.3. Valvular disease
3. Pulmonary hypertension owing to lung diseases and/or hypoxia
 - 3.1. Chronic obstructive pulmonary disease
 - 3.2. Interstitial lung disease
 - 3.3. Other pulmonary diseases with mixed restrictive and obstructive pattern
 - 3.4. Sleep-disordered breathing
 - 3.5. Alveolar hypoventilation disorders
 - 3.6. Chronic exposure to high altitude
 - 3.7. Developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
- 1'. Pulmonary hypertension with unclear multifactorial mechanisms
 - 5.1. Hematologic disorders: myeloproliferative disorders, splenectomy
 - 5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis; lymphangioleiomyomatosis, neurofibromatosis, vasculitis
 - 5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
 - 5.4. Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK1, activin receptor-like kinase type 1; BMPR2, bone morphogenetic protein receptor type 2; HIV, human immunodeficiency virus. From Simonneau G, Robbins IM, Beghetti M, et al: Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol* 2009; 54:S43-54.

pulmonary vasculature are more marked, including significant intimal hypertrophy with fibrosis, marked smooth muscle hypertrophy, vasoconstriction, adventitial proliferation, and thrombosis *in situ*.¹ These changes cause vascular flow obstruction and eventually lead to abnormal angiogenesis and formation of plexiform arteriopathy. Endothelial dysfunction also develops with an imbalance between vasodilation and vasoconstriction and between apoptosis and proliferation, mechanisms that are thought to play the most important role in the development of chronic progressive

PH. Hypoxemic pulmonary vasoconstriction is an important determinant of arterial PH in patients with respiratory disorders.¹ In many types of PH, production of endogenous vasodilators (nitric oxide [NO] and prostacyclin) is impaired and production of vasoconstrictors (endothelin-1, thromboxane A) is increased.¹ That is why the common treatment strategy for PH is to achieve the balance in key molecular pathways by increasing available NO and prostacyclin, or reducing the effects of endothelin-1. Acute cases are characterized by sudden increase in pulmonary arterial pressure (PAP) as seen when mechanical obstruction with subsequent vasoconstriction develops during an acute PE. In ARDS, both hypoxemia and the accumulation of intravascular fibrin and cellular debris contribute to subsequent vascular obliteration and PH.² Endotoxin and vasoactive mediators related to pulmonary vasoconstriction also play significant roles in development of the PH during sepsis. Several animal studies have shown that endotoxin may cause not only systemic hypotension but also pulmonary biphasic hypertension, decrease in compliance, and increase in resistance of the respiratory system.³ Those endotoxin-dependent hemodynamic and respiratory effects are mediated by excessive release of inflammatory mediators and imbalance in production of NO, prostanoids, and endothelin-1.^{3,4} PH in endotoxemia is characterized by a constriction of proximal pulmonary arteries during the early phase followed by decreased compliance of distal pulmonary vasculature.⁵ Endotoxin infusion can also dramatically affect right ventricular function: in the very early phase of endotoxemic shock, right ventricular-vascular coupling is preserved by an increase in right ventricular contractility. Later, myocardial oxygen consumption and the energy cost of right ventricular contractility are increased, which along with progressive endotoxin-induced PH lead to right ventricular dysfunction and failure.⁶

RIGHT VENTRICULAR FAILURE

The right ventricle (RV) differs from the left ventricle (LV) in morphologic appearance and functionality.⁷ Despite the requirement for a similar cardiac output between the RV and LV, the bioenergetic requirement for right ventricular function is approximately 20% of the LV. The RV is thinner than the LV and its shape differs from that of the LV, having a crescent-shaped morphologic appearance. These differences reflect the low resistance, low impedance, and high compliance of the pulmonary circulation.⁷ The high compliance allows quick adaptations to changes in preload; however, unlike the LV, the RV tolerates poorly the acute increases in afterload, which could lead to hemodynamic collapse.⁸ It is important to emphasize these differences between the ability of the RV to adapt to sudden (acute) versus gradual (chronic) elevation of PAP. A normal RV can acutely adapt to high flow, but is barely able to tolerate any but very short acute high-pressure load.⁹ The normal RV cannot acutely increase the mPAP to more than 40 mm Hg.¹⁰ In chronic sustained elevation of afterload as seen in PH, the RV increases its wall thickness by hypertrophy of the muscle mass and assumes a more rounded shape (Fig. 45.1). Eventually and despite the compensatory right ventricular hypertrophy to the sustained long-term pressure overload, the RV dilates. Neurohormonal activation develops during

Figure 45.1 RV configuration in health (left, **A**) and pulmonary hypertension (right, **B**). IPAH, idiopathic pulmonary artery hypertension; LV, left ventricle; RV, right ventricle. (Modified with permission from Bogaard HJ: The right ventricle under pressure. *Chest* 2009;135:794-804.)

the right ventricular dilatation and is an important mechanism in both acute and chronic right ventricular failure. The consequence of sympathetic hyperactivity is an increase in PVR with impedance of flow, causing right ventricular strain that impairs filling and causes right ventricular volume and pressure overload. Furthermore, the RV dilatation increases oxygen consumption and reduces contractility, which is going to decrease right ventricular perfusion, and a vicious circle develops that ultimately leads to death. Tricuspid regurgitation develops as a result of right ventricular dysfunction and defines a poor prognosis.¹¹ It is important also to mention the concept of functional interdependence between the RV and the LV. Anatomically, the superficial myocardial fibers encircle both ventricles, and both chambers are contained within the pericardium, sharing the interventricular septum.¹² During elevation of right-sided heart pressures, the interventricular septum shifts progressively to the left with subsequent development of left ventricular diastolic dysfunction that reduces the LV's cardiac output and coronary perfusion pressure.^{8,13} A downstream adverse effect of right-sided heart failure is the development of systemic venous hypertension leading to concomitant visceral organ congestion and dysfunction. Regardless of the underlying cause of PH, the final common pathway for hemodynamic deterioration and death is right ventricular failure.

CLINICAL CLASSIFICATION OF PULMONARY HYPERTENSION

The classification of PH has presented different modifications since its first classification made in 1973 at a conference endorsed by the World Health Organization. The most recent classification of PH, described in [Box 45.1](#), is based on causative diseases and was updated during the Fourth World Symposium on PH held in Dana Point, California.¹⁴ For the intensivist, it is important to recognize two different scenarios: patients with chronic PH admitted to the ICU for an acute process that may or may not worsen the underlying

Box 45.2 Etiology of Pulmonary Hypertension in the Intensive Care Unit

Acute and Acute-on-Chronic Venous Pulmonary Hypertension

Pulmonary hypertension secondary to left ventricular dysfunction/failure with left atrial hypertension:

- Congestive heart failure, acute myocardial infarction, diastolic dysfunction, severe valvular disease (e.g., mitral regurgitation, mitral stenosis)
- Pulmonary venoocclusive disease (VOD)

Acute-on-Chronic Arterial Pulmonary Hypertension

Worsening of preexisting pulmonary hypertension, usually with respiratory or cardiovascular decompensation, by either of two mechanisms:

- Natural progression
- Precipitation by acute condition (e.g., sepsis/ARDS, PE, drugs)

Acute Arterial Pulmonary Hypertension

Without preexisting pulmonary hypertension:

- Massive PE
- ARDS, sepsis, drug-induced, others

ARDS, acute respiratory distress syndrome; PE, pulmonary embolism.

From Tsapenko MV: Arterial pulmonary hypertension in noncardiac intensive care unit. *Vasc Health Risk Manag* 2008;4:1043-1060.

PH and patients with no history of chronic PH who develop acute PH during their ICU stay secondary to various conditions. It is also important to distinguish between pulmonary arterial hypertension as seen in IPAH and pulmonary venous hypertension as seen in left ventricular failure. A classification of PH in the ICU is described in [Box 45.2](#).

ACUTE ON CHRONIC PULMONARY HYPERTENSION

Individuals with preexisting PH (i.e., IPAH or portopulmonary hypertension [group 1]) are particularly vulnerable to acute illnesses, which commonly result in rapid clinical deterioration and even death.¹⁵ Besides the entities described in group 1 of the Dana Point classification, several other conditions that are associated with chronic PH and are more commonly encountered in the ICU include left ventricular heart failure (with or without preserved ejection fraction causing pulmonary venous hypertension; group 2); interstitial lung diseases, chronic obstructive pulmonary disease (COPD), chronic hypoventilation syndromes, and sleep disorder breathing (group 3); and chronic pulmonary thromboembolic disease (group 4). Several clinical factors faced during intercurrent critical illness can aggravate or unmask the hemodynamics of patients with preexisting PH and are outlined in [Table 45.1](#). These patients with chronic PH can rapidly deteriorate and usually die from progressive right ventricular failure (49%), progressive respiratory failure (18%), or sudden cardiac death (17%). Cardiopulmonary resuscitation (CPR), even when attempted in the hospital

Table 45.1 Intensive Care Unit (ICU) Factors Associated with Worsening Hemodynamics in Pulmonary Hypertension

Pulmonary	Cardiac	Vascular
Hypercapnia	Volume overload	Use of systemic vasopressors
Hypoxemia	Pulmonary venous hypertension (left ventricle failure)	Vasoconstrictor/vasodilator imbalance
Acidosis	Increased right to left shunting	Endothelial injury
High airway pressure	Right ventricle strain	Vascular microthrombosis
Decreased compensatory capacity	Use of inotropes	Vascular remodeling

setting, is rarely successful. Only 6% of patients survived for more than 90 days and most of the survivors had identifiable causes of circulatory arrest that were rapidly reversible. The pulmonary blood flow is virtually absent in these patients during CPR. In 54%, cardiorespiratory arrest was associated with an intercurrent illness,¹⁵ illustrating how preexisting PH adversely affects patients' compensatory capacity and ability to survive an acute illness.

ACUTE PULMONARY HYPERTENSION

Acute PH is caused by an abrupt increase in PVR. The prototype of this process is an acute PE; however, other conditions frequently seen in the ICU can also be associated with acute increase in PVR such as acute decompensated left ventricular failure, post cardiac surgery, ARDS, and sepsis.¹⁶ Acute right ventricular failure develops in 61% of patients who present with massive PE that involves at least two lobar arteries. The mortality rate ranges from 3% in hemodynamically stable patients to 59% in unstable ones.^{17,18} Hemodynamic instability in the setting of PE is defined as systolic blood pressure (SBP) less than 90 mm Hg or a drop in SBP greater than 40 mm Hg from baseline for more than 15 minutes that is not otherwise explained by hypovolemia, sepsis, or new arrhythmia.¹⁸ The degree of shock inferred from the presence of metabolic acidosis, but not transthoracic echocardiography (TTE) findings, is the most powerful predictor of death in these patients.^{17,19}

ACUTE RESPIRATORY DISTRESS SYNDROME AND SEPSIS

Right ventricular dysfunction as a complication of ARDS is more gradual than in patients with massive PE, usually occurring at least 48 hours after the beginning of respiratory support.¹⁶ Evaluation of right ventricular function by TTE in a group of 75 ARDS patients submitted to protective ventilation demonstrated 25% incidence of acute right ventricular failure, resulting in detrimental hemodynamic consequences associated with tachycardia. However, those changes in heart function were reversible in patients who recovered; furthermore, it did not increase mortality rate.¹⁶ Although the initial magnitude of PH was not an indicator of mortality rate, mPAP increased in nonsurvivors, but not in survivors when followed for 7 days.²⁰ Thus, development of PH in ARDS patients seems to be a sign of poor prognosis. In another cohort of 352 ARDS patients, both mortality rate and incidence of right ventricular failure were related to the level of plateau pressure during mechanical

ventilation. In patients without acute cor pulmonale, the odds ratio of mortality for an increase in plateau pressure from 18–26 to 27–35 cm H₂O was 1.15 ($p = 0.635$); however, for patients with acute cor pulmonale, the odds ratio of mortality for an increase in plateau pressure from 18–26 to 27–35 cm H₂O was 3.32 ($p = 0.034$), suggesting that the threshold for a safe plateau pressure depends on the presence or not of acute cor pulmonale.²¹ Importantly, the implementation of low tidal volume ventilation in patients with ARDS has significantly lowered not only mortality rates but also incidence of acute right ventricular failure in this patient population.¹⁶ In addition to being the major risk factor for ARDS development, sepsis itself can sometimes lead to severe acute arterial PH.²²

POSTSURGICAL PULMONARY HYPERTENSION

Some surgical interventions, in particular vascular, cardiac, and thoracic surgery, may cause acute elevation of mPAP either during the surgery or shortly after the intervention has been completed. This is particularly dangerous in patients with preexisting PH, because even short-lasting increased pressure overload to the RV could lead to profound decompensation with all downstream negative hemodynamic consequences. Preexisting PH is one of the major risk factors for morbidity and death in cardiothoracic surgery patients.²³ PH is a major determinant of perioperative morbidity and mortality rate in special situations such as heart and lung transplantation, pneumonectomy, and ventricular assist device placement.²⁴ The elevated PAP during and after surgery is thought to develop secondary to acute left-sided heart failure/dysfunction, or it can also be a consequence of pulmonary parenchymal and endothelial injury with activation of the systemic and pulmonary inflammatory response to cardiopulmonary bypass circulation or ischemia-reperfusion.²⁵ Protamine-mediated acute PH and right ventricular failure in the perioperative period are common complications of cardiopulmonary bypass circulation during open-heart operations.²⁶ PH can also develop later as a result of ARDS²⁷ or other complications (sepsis, PE, etc.) not directly related to either surgery or anesthesia.

INTEGRATED APPROACH TO THE DIAGNOSIS OF PULMONARY HYPERTENSION

When PH is suspected based on presentation, examination, and risk factors, a comprehensive and structured evaluation

should be performed. Physical examination is usually variable and nonspecific. The presence of an accentuated pulmonary component of S_2 , an early systolic click, and a midsystolic ejection murmur from turbulent pulmonary outflow should raise the suspicion. Left parasternal lift and an S_4 are signs of right ventricular hypertrophy. Distended jugular veins and hepatjugular reflux indicate high central venous pressure. Right ventricular S_3 , hepatomegaly, ascites, systemic hypotension, peripheral edema, and cool extremities are all signs of right ventricular failure. A high level of suspicion is paramount in establishing a timely diagnosis of PH in order to initiate therapy. The diagnostic endeavor is aimed at making the diagnosis of PH and also in finding its cause. General guidelines for the evaluation of PH are described in detail in [Figure 45.2](#). Chest radiographic

findings are usually nonspecific but enlarged main and hilar PA shadows could be seen. RV enlargement best seen in the lateral views could also suggest PH. Moreover, the chest radiograph can also present findings of underlying primary lung disease such as emphysema or pulmonary fibrosis. Electrocardiography has a low sensitivity and specificity for the diagnosis of PH; however, evidence of right atrial enlargement, right axis deviation, and RV enlargement is suggestive of the disease. In many cases, PH remains undiagnosed and its treatment begins only after serious complications have developed. Some serologic markers, such as troponin and natriuretic peptides, are important for the evaluation of right ventricular dysfunction. Serum troponin may be elevated in patients with PH and has been associated with right ventricular overdistention and

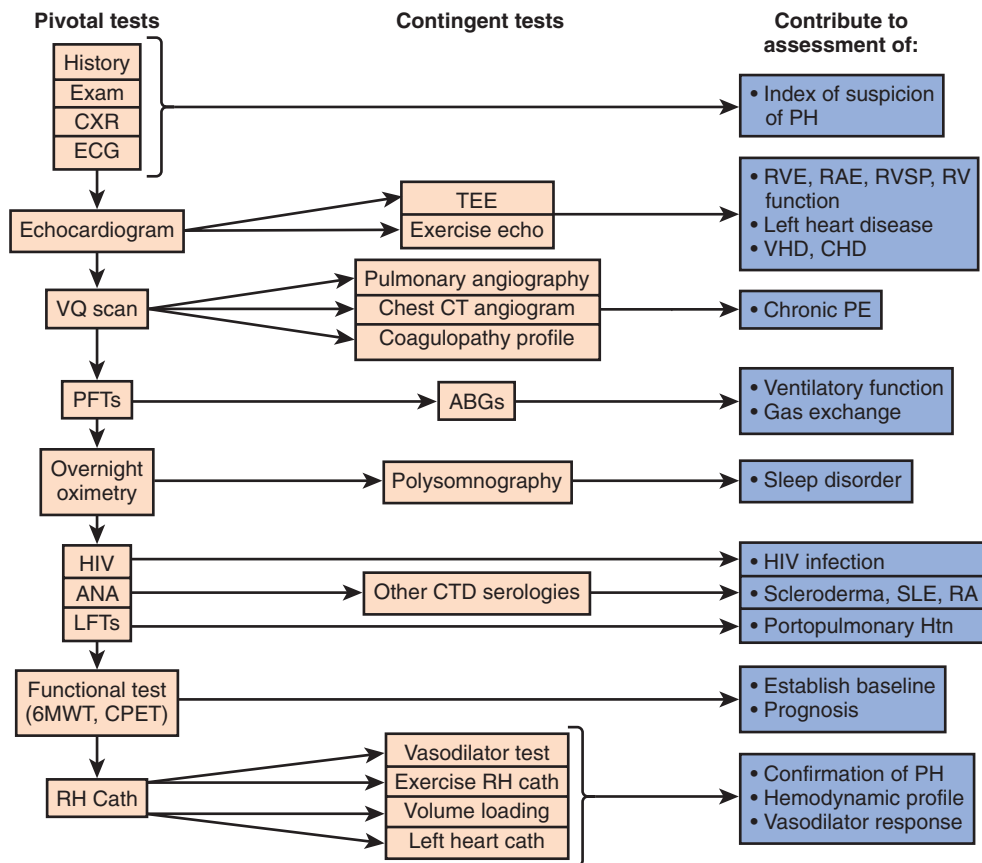

Figure 45.2 General guidelines for the evaluation of pulmonary hypertension: because the suspicion of PH may arise in various ways, the sequence of tests may vary. However, the diagnosis of PAH requires that certain data support a specific diagnosis. In addition, the diagnosis of IPAH is one of excluding all other reasonable possibilities. Pivotal tests are those that are essential to establishing a diagnosis of any type of PAH either by identification of criteria of associated disease or exclusion of diagnoses other than IPAH. All pivotal tests are required for a definitive diagnosis and baseline characterization. An abnormality of one assessment (such as obstructive pulmonary disease on PFT), does not preclude that another abnormality (chronic thromboembolic disease on \dot{V}/\dot{Q} scan and pulmonary angiogram) is contributing or predominant. Contingent tests are recommended to elucidate or confirm results of the pivotal tests and need only be performed in the appropriate clinical context. The combination of pivotal and appropriate contingent tests contributes to assessment of the differential diagnoses in the right-hand column. It should be recognized that definitive diagnosis may require additional specific evaluations not necessarily included in this general guideline. 6MWT indicates a 6-minute walk test. ischemia. Troponin I leak due to acute right ventricular strain from PE has been well studied and may predict mortality rate.^{28,29} Elevated B-natriuretic peptide (BNP) is an important prognostic indicator and correlates strongly with PVR, cardiac output, and functional status in patients with PH.³⁰ A high level of plasma BNP, and in particular, a further increase in plasma BNP during follow-up, may have a strong independent association with increased mortality rates in patients with PH.³¹ However, the significance of measuring BNP level in patients with PH in the acute setting remains unclear.

The most useful tools for the diagnosis and management of PH are echocardiography and right-sided heart catheterization.

ECHOCARDIOGRAPHY

Echocardiography is the most important and useful noninvasive study for screening of PH. It is very important for diagnosing and determining the degree and clinical significance of PH in critically ill patients. It can noninvasively visualize cardiac anatomy and certain intracardiac shunts and valvular abnormalities, estimate right atrial and pulmonary arterial pressures, determine the severity of right and left ventricular dysfunction and wall motion abnormalities, and reveal other potential causes of PH. In the absence of pulmonary outflow obstruction, PA systolic pressure is equivalent to right ventricular systolic pressure (RVSP), which can be calculated from measured systolic regurgitant tricuspid flow velocity and estimated right atrial pressure. PH by TTE is usually defined as RVSP greater than 35 mm Hg with the expected upper normal limit up to 40 mm Hg in older or obese subjects.³² However, it has limitations and echocardiography has a 45% false-positive rate of diagnosis when patients subsequently undergo right-sided heart catheterization.³³

Among 3790 healthy people who underwent TTE, RVSP was highly variable in the range of 15 to 57 mm Hg and was associated with age, body mass index (BMI), gender, wall thickness, and ejection fraction. An RVSP greater than 40 mm Hg was found in 6% of those older than 50 years and 5% of those with a BMI greater than 30 kg/m².³² Therefore, not every elevation of RVSP indicates the presence of a pathologic condition. Possible explanations for mildly elevated RVSP detected by TTE include³⁴ (1) overestimation of the RVSP in a patient with true normal pulmonary pressure; (2) serendipitous observation of a transient pressure elevation in an otherwise healthy individual; (3) discovery of stable mild PH, and (4) discovery of early progressive PH.

Echocardiographic signs of significant PH include right ventricular dilation (D-shaped RV) and its hypertrophy (in sustained cases), septal dyskinesia and bowing into the LV during late systole to early diastole, RV hypokinesia, tricuspid regurgitation, right atrial enlargement, and a dilated inferior vena cava.^{19,35,36} In patients with chronic PH, predictors of poor outcome include right atrial enlargement, septal bowing, and the development of a pericardial effusion.³⁷ Increased RV size combined with increased outflow resistance and reduced ejection fraction have been also described in acute right ventricular failure.¹⁹ A specific pattern of right ventricular dysfunction in acute PE has

been characterized by a severe hypokinesia of the RV mid-free wall, with normal contractions of the apical segment.³⁸

Images may be suboptimal in critically ill patients because of limitations related to the patient's general condition, limited positioning, attached monitoring devices, wound dressings, or ventilatory support. Transesophageal echocardiography (TEE) may be more accurate and sensitive in critically ill patients than TTE, especially in acute diseases such as PE when acute PH is highly suspected.³⁹ Newly developed handheld ultrasound devices capable of TEE may sufficiently replace a standard cart-based TEE system in unstable critically ill patients.⁴⁰ Advanced Doppler echocardiographic techniques allow for comprehensive hemodynamic assessment of the patients with PH. A high correlation between PA catheter and Doppler echocardiography evaluations of cardiac output, transpulmonary gradient, and PVR were observed in patients with severe PH.⁴¹

RIGHT-SIDED HEART CATHETERIZATION

Invasive hemodynamic assessment using right-sided heart catheterization is considered the gold standard for the diagnosis of PH³⁵; however, this procedure must be performed thoroughly and accurately. Besides direct measurement of the hemodynamic parameters, it also provides useful information regarding response to vasodilator therapy. Analysis of mixed venous oxygen saturations during passage of the PA on its way through the cardiac chambers can allow diagnosis of intracardiac shunts. A PCWP measurement reflects left ventricular end-diastolic (filling) pressure. Values less than 15 mm Hg rule out left ventricular, valvular, and pulmonary venous diseases as possible causes of the PH.³⁵ It is important to emphasize that misinterpretation of the PCWP is a common pitfall during right-sided heart catheterization and it should be measured at the end of expiration and in several segments of the pulmonary vasculature because pulmonary veno-occlusive disease can cause elevated wedge pressure only in affected segments.⁴² In the ICU, placement of a PA catheter for diagnosis and monitoring is highly desirable in patients with severe PH and in patients with progressive heart failure.⁴³ Although there is a little doubt that the hemodynamic data are valuable in the care of critically ill patients with acute conditions complicated by PH, there are no data available on how PA pressure monitoring could affect management and outcome of these patients. Indeed, placing a PA catheter could be a challenging and dangerous procedure in such patient populations. Technical difficulties could be related to severe tricuspid regurgitation, right ventricular dilatation, elevated PAP, and decreased cardiac output. Complications of PA catheterization are particularly dangerous in patients with PH and right ventricular dysfunction/failure. Arrhythmias in response to PA catheterization can have potentially life-threatening consequences by decreasing cardiac output, or converting into fatal ventricular arrhythmias. Obtaining a PCWP may be technically difficult in patients with markedly elevated PAP and also carries a high risk of sometimes fatal pulmonary arterial rupture. Finally, the presence of tricuspid regurgitation can significantly decrease accuracy of cardiac output calculations by thermodilution. Theoretically, the Fick method may be more accurate, but in

critically ill patients with increased pulmonary metabolism and high or very low cardiac output, its accuracy may not be optimal.⁴⁴

MANAGEMENT OF ARTERIAL PULMONARY HYPERTENSION AND RIGHT VENTRICULAR FAILURE IN THE INTENSIVE CARE UNIT

GENERAL MANAGEMENT PRINCIPLES

In patients with preexisting PH, an acute illness can lead to significant hemodynamic changes with profound and refractory systemic arterial hypotension, mainly secondary to increased PVR associated with decreased cardiac output and decrease systemic vascular resistance (SVR). This would require tight hemodynamic monitoring and aggressive treatment with combinations of pulmonary vasodilators, inotropic agents, and systemic arterial vasoconstrictors to manage acute right ventricular dysfunction and failure and also to maintain coronary and end-organ perfusion.⁴⁵ The first step is to optimize the volume status and avoid volume overload. Then efforts should be made to achieve the following: improve cardiac output, reduce PVR (by using vasodilators with fewer systemic effects and \dot{V}/\dot{Q} mismatch);

treat reversible factors such as hypoxemia, acidosis, anemia; and maintain adequate SVR to ensure end-organ perfusion and adequate coronary filling pressures.⁴⁶ A general therapeutic approach to pulmonary hypertension in the ICU is outlined in Figure 45-3.

MONITORING

ICU monitoring of PH and right ventricular failure is of paramount importance. Besides the utilization of a PA catheter as outlined previously, serial TTE could also be useful for assessment of right ventricular function. Additionally, close attention should be made to monitoring end-organ function. Urinary output and serum creatinine should be used to monitor renal function. Liver function tests should also be followed closely for assessment of liver impairment, especially during severe right ventricular failure and development of passive liver congestion.

Previous studies have raised concerns and controversy regarding the use of PA catheters and their utility for invasive measurement of cardiac function in critically ill subjects with shock.^{47,48} However, individuals with severe PH and right ventricular failure are probably best monitored by an invasive method to allow continuous measurement of key hemodynamic values such as cardiac index, mPAP, PVR, and SvO_2 . General markers of tissue perfusion such as lactate

levels and neurohormonal/myocardial markers such as natriuretic peptides and troponin can also be utilized for monitoring.

FLUID MANAGEMENT

Fluid management is a difficult task in these patients because both hypervolemia and hypovolemia can have severe effects on the overall hemodynamic status. With a normal RV, the right ventricular ejection fraction is usually dependent on right ventricular preload.⁴⁹ However, when right ventricular afterload is increased, even a relatively small increase in blood volume may result in right ventricular dysfunction. Right ventricular dysfunction can occur with volume expansion, despite constant PVR and a decrease in mPAP. Further observations have drawn the conclusion that high right ventricular filling pressure restores normal hemodynamics only if PVR is normal and right ventricular contractility is not markedly reduced.⁵⁰ In patients with PH, right ventricular dysfunction/failure can reduce left ventricular filling and lead to severe cardiogenic shock. Patients with cardiogenic shock secondary to right ventricular dysfunction usually have a very high (>20 mm Hg) right ventricular filling pressure.⁵¹ In addition to decreased right ventricular contractility and cardiac output, right ventricular dilatation can further limit left ventricular filling via ventricular interdependence shifting of the interventricular septum toward the left ventricular cavity. Traditional practice with aggressive fluid resuscitation can thus worsen the patient's condition. The challenge in fluid management in those patients is to find the optimal right ventricular preload to avoid the detrimental effects of ventricular interdependence on left ventricular function. In the majority of cases (but not in all), right ventricular failure is generally associated with fluid overload and measures should be made to achieve a negative fluid balance.⁵² Hemodynamic monitoring in patients with right ventricular failure due to acute right ventricular myocardial infarction showed that the cardiac and stroke indexes increased and the RV reached its maximum stroke work index when the filling pressure was 10 to 14 mm Hg. These values may be regarded as the optimal level of RV filling pressure in patients with right ventricular infarction.⁵³ There are no data on optimal right ventricular filling pressure in patients with right ventricular dysfunction secondary to acute PH.

OXYGENATION AND VENTILATORY SUPPORT

Adequate oxygenation is a key intervention, as pulmonary arterial hypoxic-induced vasoconstriction is common in these individuals, and might be aggravated also by acidosis as seen in acute and chronic hypercapnia or in severe shock with lactic acidosis. Optimal supplemental oxygen management is an integral component of PH therapy in the ICU.⁵⁴ One hundred percent oxygen is a selective pulmonary vasodilator in patients with sustained PH, regardless of primary diagnosis, baseline oxygenation, or right ventricular function.⁵⁵ In patients with ARDS, the vascular response to oxygen was different, and administration of 100% O₂ caused the intrapulmonary shunt to deteriorate owing to the collapse of unstable alveolar units with very low

ventilation-perfusion ratios. This is in contrast to administration of 100% O₂ to patients with COPD, in whom only the dispersion of the blood flow distribution was changed, suggesting release of hypoxic pulmonary vasoconstriction.⁵⁶

Hypercapnia has been shown to induce PH in animal models. There are no data on how it could affect acute PH in humans. However, a study on healthy volunteers revealed that human pulmonary vascular responses to hypercapnia and hypocapnia consist, respectively, of constriction and dilatation that take 1.5 to 2 hours to reach a steady level. The time courses for recovery in eucapnia are similar. Hypercapnia generated a rise in cardiac output by changing heart rate; hypocapnia produced a fall in cardiac output by changing stroke volume. The finding of marked vasodilatation in response to hypocapnia demonstrates that there is normally a substantial vascular tone in the human pulmonary circulation.⁵⁷

The management of mechanical ventilation in patients with PH is often challenging due to the effects of positive airway pressure, in addition to the side effects of sedatives. Noninvasive ventilation should initially be considered; however, if intubation is required, careful attention must be paid to the effects of the sedatives on the hemodynamics and to the interaction of the patient with the ventilator. Controlled ventilation alters right ventricular function primarily by increasing right ventricular afterload during the lung inflation period.⁵⁸ Transpulmonary pressure (and related tidal volume), but not airway pressure itself, was the main determinant factor of right ventricular afterload during mechanical ventilation.⁵⁹ This supports low-volume strategy in ARDS, recommended as a protective measure for lung parenchyma, which might also represent a protective measure for the RV and pulmonary circulation.⁵⁹ Frequency of acute right ventricular failure in ARDS patients declined from 61% to 25% over the last 15 to 30 years, which could be explained in part by fundamental alterations in respiratory support and implementation of low tidal volume ventilation.¹⁶ Lower incidence of acute right ventricular failure in ARDS patients was associated with lower (<27-30 cm H₂O) plateau pressures.²¹ Right ventricular systolic function was generally negatively affected by positive end-expiratory pressure (PEEP) in ARDS patients undergoing mechanical ventilation. In those patients, PEEP titration significantly affected right ventricular outflow impedance, the lowest values of which were associated with the achieved better total quasi-static lung compliance (calculated by dividing tidal volume by the difference between plateau and end-expiratory airway pressures).⁶⁰ This suggests that lung hyperinflation along with either inadequate or excessive PEEP can significantly reduce right ventricular systolic function and cardiac output. On other hand, in an experimental study on healthy animals, the open lung concept ventilation resulted in significantly improved lung aeration with no negative effect on right ventricular afterload or left ventricular afterload. This is possibly explained by a loss of hypoxic pulmonary vasoconstriction due to alveolar recruitment. The reductions in the cardiac output and in the mPAP were the consequences of a reduced preload.⁶¹ A clinical study in patients after cardiac surgery also found no evidence that ventilation, according to the open lung concept, affects right ventricular afterload.⁶²

VASOPRESSORS AND INOTROPIC AGENTS

The choice of any particular agent in patients with PH should take into consideration its effects on PVR and cardiac output when used alone or in combination with other agents. Most traditional vasopressors and inotropes have not been studied in the setting of arterial PH and hemodynamic instability.

Dobutamine is the most commonly used inotropic agent in patients with PH. It augments myocardial contractility and reduces left ventricular afterload via peripheral vasodilatory effects. In low doses (up to 5 $\mu\text{g}/\text{kg}/\text{minute}$) dobutamine decreased PVR, lowered mean systemic arterial pressure, and slightly increased cardiac output⁶³; at doses of 5 to 10 $\mu\text{g}/\text{kg}/\text{minute}$, dobutamine caused significant tachycardia and systemic hypotension without improving PVR.^{63,64} In cases of systemic hypotension patients may require concomitant use of norepinephrine or other peripheral vasoconstrictors to maintain appropriate systemic perfusion pressures. A combination of inhaled nitric oxide (INO) and dobutamine infusion produced an additive effect on pulmonary circulation⁶³ with increased cardiac performance and improved oxygenation⁶⁵ and had no adverse effects on systemic hemodynamics. In an animal model of acute right ventricular failure secondary to acute PH, dobutamine was superior to norepinephrine in improving right ventricular function by optimizing pulmonary vasodilation and improving right ventricular contractility.⁶³

Norepinephrine (NE) is widely used in critical care settings to treat hemodynamically unstable patients. It exerts significant inotropic effects via β_1 -receptor agonism and α_1 -receptor-mediated vasoconstriction. In addition to positive effects on cardiac output and systemic arterial pressure, NE is able to improve the right ventricular oxygen supply/demand ratio,⁶⁶ although it increases PVR and could worsen PH.⁶⁷ However, at a lower dose ($<7 \mu\text{g}/\text{minute}$), NE exerts more vasoconstrictive effect in systemic than in pulmonary circulation.⁶⁷ NE was superior to *phenylephrine* in restoring systemic arterial pressure, decreasing PVR, augmenting right ventricular myocardial blood flow, and improving cardiac output in animal models of acute PE.⁶⁸ In patients with chronic PH who developed systemic hypotension following induction of anesthesia, NE in contrast to *phenylephrine* decreased the ratio of PAP to systemic blood pressure without a change in cardiac index.⁶⁷ Experimental data also showed that α -adrenergic stimulation can cause a disproportionate rise in PVR,⁶⁹ which is implicated in the development of acute PH in critical illnesses. Besides this, *phenylephrine* also causes bradycardia with further adverse consequences on pulmonary and systemic hemodynamics.⁷⁰ These findings all make NE preferable over *phenylephrine* for the treatment of hypotension in patients with chronic PH.⁶⁷ Moreover, NE can be used successfully in combination with selective pulmonary vasodilators for the treatment of patients with acute and chronic PH.^{45,71}

Dopamine produces dose-dependent dopaminergic, β - and α -adrenergic effects on cardiac output and vascular tone. In patients with chronic PH, dopamine infusion led to increased heart rate, mean pulmonary and systemic pressure, and cardiac index with concomitant fall of SVR.⁷² However, administration of dopamine, similar to *epinephrine*,

is associated with high risk of tachyarrhythmia, with potentially dramatic hemodynamic consequences in patients with severe PH.⁷⁰ In a small animal study of sepsis-induced PH, *epinephrine* infusion increased SVR and cardiac output and lowered PVR.⁷³ *Isoproterenol* is another agent that has positive inotropic and chronotropic effect, which in therapeutic doses increases cardiac output and produces pulmonary and peripheral vasodilation. In animals with acute PH, administration of *isoproterenol* did not reduce PAP, and instead produced significant tachycardia and was associated with arrhythmias.⁷⁴

Vasopressin is an endogenous hormone with a weak noradrenergic vasopressor effect on the systemic vasculature and an ability to produce NO-mediated selective pulmonary vasodilation.⁷⁵ In healthy animals, a linear relationship was observed between vasopressin levels and SVR without significantly affecting PVR or any vascular compliance.⁷⁴ It was very effective (at a dose of 0.1 U/minute) in treating refractory low SVR hypotension concomitant with PH in postoperative patients.⁷⁶ Experimental data on the use of vasopressin in acute PH is controversial. In one setting, vasopressin infusion produced significant pulmonary vasodilation,⁷⁷ although at a higher dose (1.16 U/kg/hour) in another animal model it caused increased PVR and decreased cardiac output with a decrease in right ventricular contractility.⁷⁸ Studies of the coronary vasoconstriction and the inotropic effect of vasopressin are also controversial, and the effects appear to depend on the dose used and the model studied.⁷⁹ However, the use of vasopressin at a low dose (0.04 U/minute) produces favorable hemodynamic effects without substantial decline in cardiac output and pulmonary vasoconstriction,⁷⁹ which makes it a preferable agent for patients with PH.

Levosimendan (a myocardial and vascular calcium sensitizer) besides positive systemic hemodynamic effects also has pulmonary vasodilatory properties and positive inotropic effects on the RV. This makes it particularly effective in treatment of right ventricular dysfunction related to PH.^{80,81} In this setting, it restored right ventricular function even better than dobutamine, mainly because of more efficient pulmonary vasodilation on top of similar inotropic effects. A pilot prospective randomized controlled study on patients with ARDS in association with septic shock showed that levosimendan improves right ventricular performance mainly through pulmonary vasodilator effects.⁸² It was also effective in restoring right ventricular function in patients with cardiogenic shock following myocardial infarction.⁸³

Milrinone is a selective phosphodiesterase-3 inhibitor with significant inotropic and vasodilatory effects in both pulmonary and systemic circulation. It is widely used alone or in combinations in patients with decompensated heart failure, particularly in those with nonischemic left ventricular systolic dysfunction,^{84,85} and those after cardiac surgery.^{1,86} In animal models of both acute and chronic PH, milrinone significantly reduced PVR and improved right ventricular function.^{87,88} In combination with INO, milrinone produced additive pulmonary vasodilation in acute PH.⁸⁹ In another animal model of PH, addition of sildenafil to milrinone produced more effective pulmonary vasodilation and increased right ventricular contractility without significant

systemic hypotension. Cardiac output and right ventricular performance were significantly improved after milrinone alone or in combination with sildenafil, but not with sildenafil alone.⁹⁰ The systemic vasodilatory effects of milrinone along with its relatively long half-life are the major limiting factors against its utilization in conditions associated with systemic hypotension or hemodynamic instability. Systemic vasopressors (norepinephrine and low-dose vasopressin) were effective in the treatment of the milrinone-induced systemic hypotension. However, a milrinone-vasopressin combination was associated with better hemodynamics than milrinone-norepinephrine during the management of right ventricular failure.⁹¹ In a volume-resuscitated pediatric patient with septic shock, a combination of catecholamines with milrinone improved cardiovascular function.⁹² In animal models, nebulization of milrinone predominantly dilated pulmonary blood vessels, resulting in a reduced pulmonary-to-systemic vascular resistance ratio, improvement in hemodynamic and oxygenation profiles, and prevention of the pulmonary endothelial dysfunction.^{93,94} Inhaled milrinone was superior to intravenous milrinone in patients with PH after mitral valve replacement surgery; demonstrating less systemic hypotension, more reduction in intrapulmonary shunt fraction, and improvement in $\text{PaO}_2/\text{FIO}_2$ ratio.⁸⁶

PULMONARY VASODILATORS

Reduction of right ventricular afterload is an important part in the management of a patient with PH. Most pulmonary vasodilators can be subdivided according to their action on the pulmonary vasculature via either cyclic guanosine monophosphate, prostacyclin, or endothelin pathways.¹ Used in stable patients either as monotherapy or in combination, they were able to reduce mortality rates and improve multiple other clinical and hemodynamic outcomes.^{95,96} Not all of them can be utilized in a critical care setting; the route of administration, half-life, and systemic effects could significantly affect the choice of the medication. Pulmonary vasodilators with longer half-lives or significant systemic hemodynamic effects can decrease organ perfusion pressure and reduce right coronary blood flow with further deterioration of right ventricular performance.

INHALED NITRIC OXIDE

INO is a potent vasodilator able to lower PAP and right ventricular oxygen demand.⁸⁸ This improves cardiac performance without altering right ventricular contractility and cardiac output in hemodynamically stable patients with a variety of causes of PH.^{87,89,97} INO also dilates pulmonary vasculature in ventilated lung areas, thereby improving \dot{V}/\dot{Q} match and oxygenation.⁹¹ It has a very short half-life and almost no systemic vasodilatory effects, which is very important in the treatment of hemodynamically unstable patients. Multiple studies on INO utilization in ARDS patients showed improvement in oxygenation for 24 to 48 hours and variable improvement in mPAP.⁹² A combination of INO and other interventions, such as PEEP and prone positioning, also had beneficial and additive effects on arterial oxygenation.⁹³ However, INO had no favorable impact on the duration of ventilatory support or mortality rate in this patient population.^{93,98} In cardiac surgery patients with

a history of PH, INO was associated with lower heart rates, higher RV ejection fraction, and a lower requirement for vasopressor agents compared to milrinone.⁹⁹ INO has been successfully used and it was associated with improved outcomes in critically ill postoperative patients who developed severe PH or right ventricular failure.^{95,100} A combination treatment of INO with other pulmonary vasodilators (milrinone, sildenafil, etc.) has been successfully used in management of acute PH in different conditions.^{89,101} Besides its high applicability in many acute conditions, INO could be delivered in spontaneously breathing individuals by face mask or even nasal cannula as it was shown in pediatric practice.¹⁰² INO treatment is associated with some side effects including methemoglobinemia^{91,96} and NO_2 formation.¹⁰³ Abrupt withdrawal of INO has been associated with rebound PH, a significant drop in PaO_2 , and life-threatening hemodynamic deterioration.^{96,104} Close monitoring and gradual discontinuation are important to prevent and detect rebound PH.

PROSTANOIDS

Prostaglandin E_1 and prostacyclin are able to produce significant pulmonary vasodilatation and lower mPAP. They also possess antithrombotic, antiproliferative, and anti-inflammatory properties. Intravenous prostacyclin is highly effective in cases of severe PH and is also associated with a significant survival benefit.^{105,106} Prostacyclin and its analogs (iloprost, epoprostenol, and treprostinil) in inhaled forms are as effective as intravenous forms in patients with chronic PH in different clinical settings.^{107,108} All prostanoids have relatively long half-lives and can significantly affect systemic hemodynamics, which limits their use in critically ill or hemodynamically unstable patients.

In the ICU setting, inhaled prostaglandins have been used to treat severe sustained PH and intractable hypoxia, but were associated with systemic hypotension. Inhaled iloprost effectively decreased mPAP and improved RV performance immediately after separation from cardiopulmonary bypass.¹⁰⁹ Inhaled iloprost was also successfully used in the treatment of acute right ventricular dysfunction in the setting of preexisting PH in heart transplant recipients during weaning from cardiopulmonary bypass circulation and was not associated with significant systemic side effects. Intravenous prostacyclin (prostaglandin I_2 [PGI_2]) in combination with norepinephrine and dopamine was effective in the treatment of protamine-mediated acute PH and right ventricular failure in the setting of open heart surgery.¹¹⁰ Inhaled prostacyclin showed different effects on oxygenation and pulmonary hemodynamics in patients presenting with primary pulmonary ARDS (reduction in $\text{PaO}_2/\text{FIO}_2$) compared with an extrapulmonary cause of ARDS (increase in $\text{PaO}_2/\text{FIO}_2$ along with a decrease in mPAP). Despite the observation that RV ejection fraction increased on INO, but not with PGI_2 , both INO and PGI_2 -aerosol showed beneficial effects on RV performance and may prove helpful in the treatment of acute PH.¹⁰⁴

PHOSPHODIESTERASE-5 INHIBITORS

Sildenafil is a specific phosphodiesterase-5 inhibitor with sustained pulmonary vasodilatory effect and the ability to lower PVR and mPAP and to increase cardiac output in patients with different forms of chronic PH,^{111,112} including

patients with PH secondary to congestive heart failure.¹⁰¹ In the chronic setting, it is highly effective alone or in combination with other pulmonary vasodilators: epoprostenol,¹¹³ iloprost,^{114,115} BNP,¹¹⁶ and INO.¹¹⁷ It was able to improve central hemodynamics and right ventricular function in ventilated patients with PH who required dobutamine administration.¹¹⁸ Its ability to augment and prolong the hemodynamic effects of other pulmonary vasodilators has been successfully used to minimize rebound PH after INO discontinuation,¹¹⁹ in weaning from intravenous vasodilators in patients after cardiac surgery¹⁰¹ as well as in chronic PH therapy,¹⁰³ and in severe right ventricular dysfunction related to chronic PH.¹¹⁹ In an animal model of another specific phosphodiesterase-5 inhibitor, zaprinast was more effective than milrinone in the management of acute PH, causing dose-dependent pulmonary vasodilation without significant systemic hypotension.¹²⁰ Intravenous zaprinast may also increase the efficacy and prolong the duration of action of INO; however, its efficacy in lung injury models was uncertain: nonselective vasodilation induced by intravenously administered zaprinast not only worsens gas exchange but also abolishes the beneficial effects of INO.¹²⁰ Sub-threshold doses (which did not reduce mPAP) of zaprinast and sildenafil in patients with acute lung injury associated with PH improved responsiveness to INO.¹²¹

Calcium channel blockers have been used in hemodynamically stable patients with PAH who demonstrated a pulmonary vascular response to acute vasodilator challenge.⁴² There are limited data on utilization of calcium channel blockers in critically ill patients with acute PH. Acute administration of nifedipine did not cause pulmonary vasodilation, and in contrast led to increased right ventricular end-diastolic pressure and decreased right ventricular contractility.¹⁰⁶ Prolonged half-life and negative inotropic effects, which may precipitate fatal worsening of right ventricular failure, limit the use of calcium channel blockers in treatment of acute PH.

Endothelin receptor antagonists appear to be highly effective in the treatment of PH in the outpatient settings.⁴² They have not been adequately studied in acute care settings. In an animal model, pretreatment with bosentan completely abolished endotoxin-induced acute PH and changes in pulmonary compliance and resistance.³ Currently, the only possible implication in critically ill patients would be weaning or conversion from inhaled or intravenous pulmonary vasodilators to oral medication (bosentan and ambrisentan). There also seems to be a role for ambrisentan in the management of portopulmonary hypertension patients awaiting liver transplantation.¹²²

Natriuretic peptides (atrial natriuretic peptide [ANP] and BNP) have diuretic and vasorelaxing properties and are able to counteract the renin-angiotensin system.¹²³ In patients with right ventricular failure, they produced dose-related pulmonary vasodilation without worsening oxygen saturation or systemic hemodynamic and exerted favorable neurohormonal effects by suppressing aldosterone. BNP significantly attenuated the mPAP and acute hypoxic pulmonary vasoconstriction in otherwise healthy individuals,¹²⁴ but had no effect on mPAP or PVR in patients with PH. Use of nesiritide in hemodynamically unstable and hypotensive patients is limited, mainly because of reduction of SVR and resulting profound systemic hypotension.¹²⁵

Nitroprusside and nitroglycerin both can cause significant pulmonary vasodilation similar to that of INO. However, nitroprusside has a longer half-life and can cause acute reduction of SVR leading to systemic hypotension, limiting its use in hemodynamically unstable and hypotensive patients.⁸⁷ A significant venodilator effect of nitroglycerin decreases right ventricular preload leading to adverse consequences in patients with right ventricular failure. Inhaled nitroglycerin may be a safer therapeutic option without adverse effect on systemic hemodynamic parameters.¹²⁶

Intravenous *adenosine* is a pulmonary vasodilator with a very short half-life (6-10 seconds) and can be effective for short-term lowering of PVR.¹⁰⁵ In the setting of acute PH, adenosine infusion may help lower mPAP without systemic hypotension, which can reverse the clinical state of shock by achieving pulmonary vasodilation.¹²⁷ At higher doses (70 to 100 mg/kg/minute) it caused systemic vasodilation.¹¹³ Adenosine is also successfully used to treat persistent PH of the newborn.¹²⁸

Dipyridamole inhibits phosphodiesterase-5 and thromboxane synthase, which explains its strong vasodilatory effect on pulmonary circulation. Dipyridamole can lower PVR, augment INO-induced pulmonary vasodilation,¹¹⁴ acutely attenuate the adverse hemodynamic effects of rapid withdrawal of INO therapy, and attenuate excessive hypoxic pulmonary vasoreactivity. In pediatric patients with PH, dipyridamole was as effective as INO, but caused significant systemic vasodilation.¹¹⁵ Intravenous dipyridamole was used in acute management of PH in combination either with INO or intravenous nitroglycerin,¹²⁹ as well as for diagnostic purposes to identify reversibility of PH in potential cardiac transplant recipients with heart failure in whom a pulmonary vasodilator response to inhalation of INO alone was not observed.¹³⁰

OTHER THERAPIES AND MECHANICAL CARDIOVASCULAR SUPPORT

The observations of survival advantage in patients with PH and a patent foramen ovale suggested that an intra-atrial right-to-left shunt could decompress the RV and increase left ventricular preload, thereby increasing systemic blood flow and improving systemic oxygen transport despite arterial oxygen desaturation. Atrial septostomy has been developed as an alternative/bridge treatment and applied in patients with lack of response to medical therapy in the absence of other surgical treatment options. It has substantial morbidity and mortality rates in critically ill patients with severe right ventricular failure.¹³¹ With growing experience, procedure-related death rates have been reduced to 5.4%, and the most suitable patient group has been identified among patients with a mean right atrial pressure between 10 and 20 mm Hg.¹³² Acute right ventricular failure after orthotopic heart transplantation was successfully managed by decompression of the RV through the patent foramen ovale of the donor heart and inhalation of iloprost.¹³³ Both pericardiectomy and creation of atrial septal defects have been used in extreme cases of acute right ventricular failure secondary to acute myocardial infarction.¹³⁴ Decompression of the RV through the septostomy may potentially be an effective alternative in the management of severe acute PH in the ICU setting. The defect could be subsequently closed

using a transcatheter septal occlusion device after the patient's condition has been stabilized.

The treatment of choice for PH secondary to chronic thromboembolic disease is pulmonary thromboendarterectomy, which can be performed when organized thrombus is in the proximal vessels¹³⁵; significant hemodynamic improvement has been reported after such intervention.

Mechanical support for the RV with RV-assist devices (RVAD) could be a reasonable option for reversible cases or as a bridge to final treatment (transplantation). In cases of acute right ventricular failure after heart transplantation, use of RVADs, extracorporeal membrane oxygenation (ECMO), femoral vein-to-femoral artery roller, or centrifugal pumps may facilitate hemodynamic stability until the transplanted heart has recovered or until a new heart has been found for retransplantation.¹³⁶ These devices could be successfully applied in other cases of potentially reversible acute PH and right ventricular failure. Intra-aortic balloon counterpulsation (IABP) has long been the mainstay of mechanical therapy for cardiogenic shock; however, not every patient has a hemodynamic response to IABP.¹³⁴ In patients with acute PH and right ventricular failure associated with systemic hypotension, IABP could improve coronary and peripheral perfusion and augment left ventricular performance with an acute decrease in afterload.¹³⁷

The use of extracorporeal life support, such as venoarterial ECMO, and pumpless lung assist devices have become the preferred bridging strategy for patients with severe right ventricular failure⁵² who are candidates for transplantation. Heart-lung and lung transplantation has been an option for the therapy of select patients with end-stage PH for the past 25 years. Currently, approximately 4% of the approximately 1700 single lung, double lung, and combined heart and lung transplants annually performed worldwide in adults are for the primary indication of PH.¹³⁸ Their long-term outcomes are comparable with patients with other primary indications for transplant.¹³⁸

PROGNOSIS

Despite significant advances made in the therapy of PH, this condition continues to have a poor survival both in the chronic and in the acute setting. The final common pathway is development of right ventricular failure and subsequent multiorgan failure. The natural history of chronic PH was well documented by the National Institutes of Health (NIH) Registry in which 194 patients with IPAH were enrolled in a multicenter observational study from 1981 through 1985.¹³⁹ The estimated median survival in this registry was 2.8 years with 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%, respectively. Studies from other countries, including Japan, India, and Mexico, have shown similar results, with a median survival estimate of 2 to 3 years. More recently, two large registries have provided more contemporary data regarding prognosis of patients with chronic PH. The French Registry recently characterized survival and important prognostic indicators in PH patients. This registry demonstrated that the survival of PH patients has improved compared to the predicted survival based on the NIH Registry, although it still remains suboptimal with 1-, 2-, and 3-year survival rates of 85.7%, 69.5%, and 54.9% for incident

cases.¹⁴⁰ In a recent large United States-based registry (REVEAL registry), important prognostic variables found to be predictors of outcome in this study included cause of PH, functional class, gender, exercise tolerance, and hemodynamics that reflect right ventricular function.¹⁴¹ Prognosis is also influenced by an underlying cause; for example, in PH associated with scleroderma, its prognosis appears to be worse than for IPAH, and the untreated 2-year survival rate may be as low as 40%.¹⁴² The presence of PH and associated right ventricular failure in the ICU is associated with worse outcomes. In the settings of both COPD and ARDS, the presence of right ventricular failure contributes significantly to shortened survival.¹⁴³ The 3-year survival rate in patients with severe airflow obstruction and a PVR three to four times normal is less than 10% to 15%.^{143,144} Death from PH depends mainly on the state of the RV, and patients with symptoms of severe right-sided heart dysfunction, such as syncope, and hemodynamic evidence of impaired right ventricular function, such as reduced cardiac output or mixed venous saturation and elevated right atrial pressure, usually surrender to the disease within 1 to 2 years.¹³⁹ It is very important to discuss the prognosis and the possibility of transplantation in addition to end-of-life care with these patients and their family members before they present to the ICU. It is also very important to take into account the limitations of current therapies and the complexity of this lethal disease.

KEY POINTS

- PH is a complex and heterogeneous pulmonary vascular disorder that leads to elevated PVR and RV failure; it is defined by a resting mPAP greater than 25 mm Hg and associated with a PVR greater than 240 dynes · second · cm⁻⁵ (or >3 Wood units) measured by right-sided heart catheterization.
- It is important to identify where the vascular insult originates: conditions that raise the postcapillary pressure (pulmonary venous pressures) such as left-sided heart failure or mitral stenosis differ significantly from conditions that primarily affect the pulmonary arteries and arterioles such as IPAH.
- For the intensivist, it is important to recognize two different scenarios: patients with chronic PH admitted to the ICU for an acute process that may or may not worsen the underlying PH, or who can progress to severe acute PH, leading to life-threatening complications that include refractory systemic arterial hypotension, severe hypoxemia, right ventricular dysfunction and failure, and ultimately cardiogenic or obstructive shock and death; and patients with no history of chronic PH who develop acute PH during their ICU stay secondary to various conditions such as PE or ARDS.
- A meticulous and comprehensive evaluation to determine the cause of PH is very important in order to clarify the prognosis and guide the treatment, which should be directed toward improving gas exchange and hemodynamics.

KEY POINTS (Continued)

- The choice of any particular vasopressor agent in patients with PH should take into consideration its effects on PVR and cardiac output when used alone or in combination with other medications.
- In hemodynamically unstable patients with preexisting PH, use of norepinephrine infusion with or without low-dose vasopressin infusion should be initiated to maintain satisfactory end-organ and coronary perfusion.
- Most of conventional pulmonary vasodilators were not tested in critical care settings. Some inhaled agents (INO, short-acting prostanoids) and infusible inotropic agents (dobutamine, milrinone) were able to alleviate PH in critically ill patients. However, they can cause significant systemic hypotension and should be used with caution in hemodynamically unstable patients.
- Mechanical support for the RV with RVAD, extracorporeal life support such as venoarterial ECMO, and pumpless lung assist devices could be reasonable options for reversible cases or used as a bridge to final treatment (transplantation). Heart-lung or lung transplantation should be considered in selected patients with severe PH.

Airway and Lung Protection

Localization of Bleeding

Hemorrhage Control

Surgery

Other Therapies

Hemoptysis varies in amount from intermittent blood-streaked sputum to massive arterial bleeding with asphyxiation or exsanguination. Massive hemoptysis is defined as the expectoration of blood from the respiratory tract in life-threatening quantities. Clinical definitions of massive hemoptysis focus on selected quantities of coughed blood between 200 and 1000 mL over 24 hours or less, with greater than 600 mL being the most common criterion.¹ Quantification of the amount of coughed blood is unreliable, often subjective, and fails to account for blood remaining in the lungs. The adverse clinical effects of hemoptysis such as impaired gas exchange, airway obstruction, or hypotension may be more relevant for defining a life-threatening condition.²

Fortunately, massive hemoptysis is rare and accounts for 4% to 18.5% of all cases of hemoptysis in recent studies.^{3,5} Incidence studies are problematic because of the use of variable definitions. Although mortality rates as high as 71%⁶ were reported in the past, mortality rates in recent studies of massive hemoptysis range from 0% to 38%.^{2,3,7}

This chapter focuses on the most common causes of massive hemoptysis, clinical manifestations, and options for management.

ANATOMIC CONSIDERATIONS

The lung is unique among the visceral organs in that it receives a dual blood supply from different circulations.

Because hemoptysis can occur from either the pulmonary or bronchial circulation, an anatomic understanding of these systems is important.

PULMONARY CIRCULATION

The pulmonary artery bifurcates into left and right main pulmonary arteries after it leaves the right side of the heart. The pulmonary circulation is a low-pressure system, but pulmonary artery pressures may rise to approach systemic pressures in pulmonary parenchymal and pulmonary vascular diseases. Nevertheless, pulmonary hypertension alone rarely causes hemoptysis.

Prospective angiographic studies for hemoptysis in which both pulmonary and bronchial circulations have been imaged do not exist. Bleeding from the pulmonary arterial circulation accounts for less than 10% of massive hemoptysis cases and has been noted in a variety of destructive pulmonary lesions including tuberculosis, lung abscess, and aspergillosis.^{2,8} Aneurysms of the pulmonary artery, arteriovenous malformations (AVMs), and pulmonary artery rupture have also been reported.

BRONCHIAL CIRCULATION

Bleeding from the higher pressure bronchial circulation has been estimated to cause 88% of the cases of massive and submassive hemoptysis.⁹ The bronchial arteries arise from the descending aorta with considerable anatomic variation.

The one or two bronchial arteries that supply each lung in the majority of individuals¹⁰ arise from the area near the first and second intercostal arteries. Particularly on the right side, the bronchial arteries may arise directly from the proximal first intercostal artery. The arteries course along the trachea, major bronchi, and bronchioles and have terminal communications with the pulmonary capillaries or pulmonary venules. The small-vessel bronchial supply to the trachea and major bronchi drains into the azygos vein with direct communication to the superior vena cava. Aneurysmal dilation of bronchial arteries (Dieulafoy's vascular malformation) has been noted in some patients with hemoptysis, and it can occasionally be visualized endobronchially and noted on bronchial arteriography.¹¹

A direct anastomotic communication between the bronchial and pulmonary arterioles has been sought to explain the preservation of lung parenchyma after injuries to the pulmonary vascular supply. Anatomic studies have found that intermeshing of pulmonary and bronchial capillary networks is the most common anastomotic arrangement that prevents pressurization of the pulmonary arterioles with systemic pressures.¹² However, in chronic inflammatory diseases of the airways, anatomic anastomoses have been found that allow direct pressurization of the pulmonary artery with systemic pressures.¹³ The extent to which these vascular communications are related to hemoptysis remains unknown.

Bronchial arteries vasodilate in the presence of cholinergic, β_2 -adrenergic, and some nonadrenergic, noncholinergic agonists. Although the effect of β_2 -agonists on the course of hemoptysis remains unstudied, the balance between improved mucociliary clearance of blood affected by β_2 -agonists and detrimental bronchial artery dilation should be considered.¹⁴ Other physiochemical maneuvers can influence bronchial blood flow—cold air causes blanching of the human airway,¹⁵ humidified air decreases bronchial blood flow compared with dry gas,¹⁶ and increased alveolar pressure decreases bronchial blood flow by applied pressure at the capillaries.¹²

NONBRONCHIAL SYSTEMIC COLLATERAL CIRCULATION

In diseases of the lung associated with inflammation, neovascularization of the lung parenchyma can occur. Although proliferation of the bronchial circulation is the most common mechanism to extend the vascular supply, an extensive network of systemic arteries may neovascularize the lung after crossing the pleural space. This most commonly occurs in diseases that produce pleural scarring, such as in aspergillomas and cystic fibrosis (CF). Anatomic studies of these collateral vessels commonly arise from the intercostal, subclavian, axillary, and phrenic arteries. However, nonbronchial collaterals have also been described from the internal mammary, thyrocervical, carotid, and even the coronary arteries. Suspicion that these vessels may be involved is heightened by recurrence of hemoptysis after bronchial artery embolization (BAE), the presence of pleural disease, and the absence of bronchial arteries supplying an area of lung parenchyma on initial bronchial arteriography.

PULMONARY VENOUS ABNORMALITIES

Bleeding from the pulmonary veins is most likely in cardiac disease such as mitral stenosis or mitral regurgitation. Focal varices of the pulmonary veins that are occasionally visualized on chest radiography, but are best identified on the venous phase of pulmonary arteriography, have been described.^{17,18}

CAUSES OF HEMOPTYSIS

Bronchiectasis, tuberculosis or its sequelae, lung cancer, and aspergilloma (mycetoma) account for the largest proportion of massive hemoptysis cases. However, almost any of the many causes of hemoptysis (Box 46.1) can become massive on rare occasions. Clues to specific diagnoses are obtained by history, physical examination, chest radiography, and chest computed tomography (CT). Additionally, it is important to consider the demographics of the patient population when considering the cause of hemoptysis. For example, there is a predominance of causes related to infectious diseases (i.e., mycobacterial or parasitic) and their long-term complications in individuals from developing and impoverished countries. In contrast, malignancies and bronchiectasis are more common causes of massive hemoptysis in developed countries.

BRONCHIECTASIS

Bronchiectasis is characterized by abnormal dilation of the bronchi with altered mucociliary clearance, persistent bacterial colonization, chronic inflammation of the bronchial mucosa, and submucosal neovascularization that predisposes to hemoptysis. Hemoptysis in bronchiectasis can present as a single life-threatening episode but is more commonly heralded by intermittent blood streaks intermixed with purulent sputum. In patients without a previous diagnosis, the evaluation can be difficult because chest radiography can be normal or alveolar filling with blood can obscure abnormalities. Diagnosis can usually be confirmed with high-resolution chest CT. Suspicion of the diagnosis warrants broad-spectrum antibiotics to cover the multiple organisms causing infection in addition to management of the hemoptysis.

Bronchiectasis is the usual cause of massive hemoptysis in patients with CF and occurs in approximately 4.1% of patients during their lifetime.¹⁹ Massive hemoptysis is more common in patients over the age of 18 years and has been associated with pancreatic insufficiency, *Staphylococcus aureus* colonization, reduced lung function, and diabetes.¹⁹ Although *Pseudomonas aeruginosa* remains the predominant pathogen associated with decline in lung function, its presence does not translate into an increased incidence of hemoptysis. Origin of the bleeding is most often upper lobe bronchial or systemic arteries. These patients are difficult to treat because of minimal pulmonary reserve in the majority of patients at the time of hemoptysis. Guidelines for treatment of massive hemoptysis in CF patients recommend empiric antibiotic coverage to include *S. aureus*, discontinuation of nonsteroidal anti-inflammatory drugs,

Box 46.1 Causes of Focal Pulmonary Hemorrhage**Iatrogenic Disorders**

Bronchoscopy
Lung biopsy
Pulmonary artery catheterization
Transtacheal aspiration
Radiofrequency ablation
Brachytherapy

Infectious Disorders

Lung abscess
Mycetoma
Necrotizing pneumonia (*Staphylococcus aureus*, gram-negative aerobes, *Legionella*, *Actinomyces* species, *Stenotrophomonas*, *Kytococcus sedentarius*, *Leptospira* species, *Yersinia pestis*, *Francisella tularensis*)
Parasitic infection (paragonimiasis, amebiasis, ascariasis, clonorchiasis, echinococcosis, hookworm infestation, strongyloidiasis, trichinosis, schistosomiasis)
Parenchymal fungal infection (aspergillosis, mucormycosis, coccidioidomycosis, histoplasmosis, maduromycosis, botryomycosis)
Tuberculosis (active or inactive)
Viral tracheitis
Herpetic tracheobronchitis

Interstitial Lung Diseases

Lymphangioleiomyomatosis
Sarcoidosis
Tuberous sclerosis
Pneumoconiosis
Langerhans cell granulomatosis

Miscellaneous Disorders

Amyloidosis
Bronchogenic cyst
Broncholithiasis
Bronchopleural fistula
Thoracic endometriosis
Foreign body

Vascular Disorders

Pulmonary embolism, infarction
Systemic cholesterol emboli
Intralobar sequestration
Pulmonary artery aneurysms
Behçet's disease, Hughes-Stovin syndrome, traumatic pseudoaneurysms
Acquired arteriovenous malformations
Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)
Takayasu's arteritis
Aortic aneurysms
Trachea-innominate artery fistulas
Scimitar syndrome
Vena cava-bronchial
Dieulafoy's disease of bronchus
Ventriculopulmonary fistulas
Hemangioma (sclerosing, cavernous, tracheal)

discontinuation of airway clearance therapies, discontinuation of aerosolized hypertonic saline, and use of BAE to control bleeding.²⁰ Although inhaled tobramycin and dornase alfa use were associated with a lower hemoptysis incidence,¹⁹ consensus was not reached on whether to discontinue these therapies in massive hemoptysis.²⁰

TUBERCULOSIS

The resurgence of tuberculosis in many parts of the world and the prevalence of global travel mandate consideration of the disease whenever hemoptysis occurs. Hemoptysis can

occur with active cavitary disease or as late sequelae of lung destruction causing bronchiectasis. Hemoptysis has also been reported in miliary tuberculosis, although the mechanism is unknown. The pathologic lesion that causes hemoptysis in tuberculosis is often Rasmussen's aneurysm, a small aneurysm of the pulmonary circulation positioned within a cavity wall. Bleeding from the bronchial circulation can also complicate bronchial erosions in active tuberculosis, and study of both circulations is occasionally necessary when resection for local disease is not possible. Although all patients suspected of having hemoptysis secondary to tuberculosis should be placed in respiratory isolation, active

pulmonary tuberculosis is found in only a third of such cases. Post-tuberculous bronchiectasis requires antibacterial therapy.

LUNG MALIGNANCY

Lung cancer is associated with hemoptysis in 20% to 30% of cases and may be the presenting manifestation.²¹ Although the clinical course of hemoptysis is often that of chronic blood-streaked sputum, massive hemoptysis may occur as a terminal event. Massive hemoptysis is most commonly associated with squamous cell type²²; cavitation within the carcinoma²³; and central endobronchial position, occasionally with invasion into the pulmonary arteries. The blood supply to most lung carcinomas is derived from diffuse neovascularization from the bronchial circulation, making BAE effective in some cases.

Other less common cancers can bleed when found in the lung. Kaposi sarcoma has a high incidence of bloody pleural effusions and hemoptysis. Angiosarcomas are vascular tumors that may bleed continuously from small tumor sites.²⁴ Choriocarcinomas may bleed profusely, particularly after initiation of chemotherapy. Metastatic disease including renal, ovarian, and breast cancer have rarely been associated with hemoptysis.

Massive hemoptysis may also result from interventions that treat lung malignancies. Endobronchial brachytherapy has resulted in massive, fatal hemoptysis and was found to be associated with direct contact of the brachytherapy applicator and tracheobronchial walls near great vessels.²⁵ Radiofrequency ablation of lung neoplasms has been associated with massive bleeding due to intraparenchymal hemorrhage and pulmonary artery pseudoaneurysm.^{26,27}

LUNG ABSCESS

Lung abscesses are commonly found in parenchymal areas prone to aspiration. The indolent course of these infections allows time for hypertrophy of the bronchial circulation within the walls of the abscess cavity. Additionally, these cavities may enlarge and erode into major pulmonary arteries and other thoracic vessels, including the aorta.²⁸ With either of these abnormalities, bleeding can be massive and recurrent. Although the abscesses are focal and amenable to surgery, the patient who chronically aspirates because of alcoholism or dementia may have other contraindications for surgery.

CHRONIC BRONCHITIS

Chronic bronchitis rarely causes massive hemoptysis, but it is a frequent cause of mild hemoptysis. The pathologic lesions responsible for bleeding are likely dilated bronchial arteries that are eroded during active inflammation of the airways.²⁹ A comprehensive management approach is required to treat hemoptysis and ensure that other lesions such as lung cancer are not present.

OTHER PULMONARY INFECTIONS

Although hemoptysis can complicate any bacterial or fungal pneumonia, massive hemoptysis is rare unless tissue necrosis

is present. Tissue necrosis is a hallmark of anaerobic, staphylococcal, and actinomycotic³⁰ pneumonias but can occur with many different bacterial causes. Septic pulmonary emboli, particularly from staphylococcal species, have a high incidence of concomitant lung cavitation.³¹ Mycotic pulmonary artery aneurysms may also be hidden within pneumonias and can be diagnosed by pulmonary arteriography or multidetector CT angiography.³²

Hemoptysis is particularly common in fungal pneumonias that invade the vasculature. Invasive *Aspergillus* can be found in nonimmunosuppressed patients with chronic obstructive pulmonary disease (COPD)³³ but is more commonly found in the persistently neutropenic patient. A characteristic radiographic pattern of cavitation and hemoptysis follows the recovery of neutrophils and should be anticipated in at-risk patients.^{34,35} The use of prophylactic surgery to resect areas of infarcted lung tissue has been advocated^{36,37} because of the high mortality rate associated with medical management of the hemoptysis. However, such surgery remains high risk, and controlled trials have not been performed. Although more rare, invasive pulmonary mucormycosis³⁸ may produce similar findings. Hemoptysis complicates primary coccidioidal infections in 15% of cases and may approach a 50% incidence in patients with chronic coccidioidal cavities. Histoplasmosis, cryptococcosis, and blastomycosis can also cause hemoptysis. Frequent and sometimes massive hemoptysis can occur with the parasitic diseases paragonimiasis,³⁹ echinococcosis,⁴⁰ strongyloidiasis, and ancylostomiasis.

PULMONARY EMBOLISM

Hemoptysis occurs in approximately 30% of patients with thrombotic pulmonary emboli. Characteristically, hemoptysis is mild and requires no specific therapy. Hemoptysis usually implies some degree of pulmonary infarction with potential disruption of either vascular supply. The suspicion for pulmonary emboli is increased in the presence of risk factors for thrombosis, multicentric bleeding, and pleuritic chest pain. Paradoxically, this cause of hemoptysis must be treated with anticoagulants to prevent propagation of venous thromboemboli. The incidence of worsening hemoptysis after heparin or thrombolytics has not been documented. Nonthrombotic emboli have also been associated with hemoptysis. Septic emboli usually respond to antibiotics alone.

ASPERGILLUS FUNGUS BALLS

Hemoptysis occurs in more than half of patients with pulmonary *Aspergillus* fungus balls.⁴¹ The cavity walls are richly vascularized by branches of the bronchial circulation, and enlargement of these cavities may also extend into large branches of the pulmonary artery. The mechanism of hemoptysis is likely multifactorial from secondary bacterial invasion of the fungal cavity, microinvasion of the cavity wall by *Aspergillus* (semi-invasive aspergillosis), or less commonly by truly invasive disease. Therapy of hemoptysis depends on the underlying cause for the cavitary lung disease.

Systemic antifungal therapy remains controversial because there is not a well-defined means to diagnose semi-invasive

disease.^{42,43} Intracavitary amphotericin B, however, instilled via a transthoracic catheter has proved successful at dissolution and sclerosis of the cavity with control of hemoptysis and is a viable option in patients who are poor surgical candidates.^{44,45} Alternatively, antifungal therapy with ketoconazole,⁴⁶ miconazole,⁴⁷ or amphotericin B⁴⁸ has been given endobronchially for fungus ball dissolution and hemoptysis control, but these techniques are effective in less than half of patients.⁴⁹ External beam radiotherapy of 3.5 Gy given once per week has been used as an adjunctive measure in nonoperable patients.⁵⁰

Surgery remains the therapy of choice in patients with adequate pulmonary reserve due to the recurrent nature of hemoptysis. Simple aspergilloma (no abnormality in surrounding lung) has an excellent response to surgical resection, most commonly a lobectomy. Complex aspergilloma with surrounding pleural and parenchymal involvement usually requires pneumonectomy and is associated with variable success.⁵¹ Fungus balls complicating sarcoidosis usually occur in patients with bilateral upper lobe cavitary disease (stage IV), in which underlying lung function prohibits resection.

CARDIOVASCULAR CAUSES

Mitral stenosis is one of the most common cardiac abnormalities that can present with hemoptysis.⁵² The risk of hemoptysis is likely related to the elevation of pulmonary venous pressure and the rapidity with which the stenosis developed. Clinical examination may reveal an opening snap or diastolic murmur. An echocardiogram should be obtained for definitive diagnosis.

Other causes of increased pulmonary venous pressure, such as mitral regurgitation or severe congestive cardiomyopathy, may also produce hemoptysis that usually presents with radiographic pulmonary edema and a prodrome of pink frothy sputum. Fibrosing mediastinitis,⁵³ pulmonary veno-occlusive disease,⁵⁴ and congenital pulmonary venous stenosis⁵⁵ are less common causes of pulmonary venous congestion.

Rarely, hemoptysis will occur from systemic venous hypertension in severe biventricular heart failure by azygous vein hypertension and dilation. Because the azygous vein drains the trachea and major bronchi, the submucosal dilated venous plexus of the trachea can be friable and produce major hemoptysis.

INTERSTITIAL LUNG DISEASE

Only a few interstitial lung diseases are prone to hemoptysis. Lymphangioleiomyomatosis (LAM) is a disease of smooth muscle proliferation around pulmonary lymphatics, airways, and vasculature. Any of the triad of hemoptysis, pneumothorax, and chylothorax should suggest the diagnosis in a woman of childbearing age.⁵⁶ The airway granulomas of sarcoidosis have also been associated with hemoptysis, although the presence of traction bronchiectasis may be a more common cause. Additionally, the erosion of calcified hilar lymph nodes into the vasculature can produce hemoptysis. Other interstitial lung diseases that cause hemoptysis usually have diffuse alveolar hemorrhage.

BRONCHOLITHIASIS

Broncholithiasis is an infrequent cause of hemoptysis. The typical patient usually has an established diagnosis of mediastinal calcification from granulomatous disease. Previous infections of histoplasmosis, sarcoidosis, or tuberculosis are most common. Broncholithiasis is diagnosed by bronchoscopy when any degree of lymph node calcification is visualized in the bronchial lumen. Symptoms of cough, chest pain, airway obstruction, and hemoptysis can be seen. Lithoptysis, coughing out a broncholith, can also confirm the diagnosis.

Therapy of hemoptysis involves broncholith removal. Broncholith removal by rigid or flexible bronchoscopy is usually successful when the broncholith is free. When broncholiths are partially embedded in the airway wall, removal is best facilitated by rigid bronchoscopy⁵⁷ or by thoracic surgery. Surgical options include lymph node resection with or without bronchoplasty or lobectomy. One surgical series had a 34% complication rate and a 15% rate of recurrent or persistent disease.⁵⁸

DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse alveolar hemorrhage (DAH) most commonly presents abruptly and may or may not be associated with frank hemoptysis. The early manifestations are often confused with other alveolar filling processes such as pulmonary edema, bacterial pneumonia, or the acute respiratory distress syndrome (ARDS). Consideration of DAH is prompted by the presence of diffuse infiltrates on chest radiograph, the presence of systemic manifestations of vasculitis, the association of hemoptysis, hypoxemic respiratory failure, and the common finding of anemia.⁵⁹ Unfortunately, the many causes of DAH are often differentiated on the basis of laboratory tests that may not be routine in many hospitals. Furthermore, specific therapy is often not initiated until a definitive diagnosis has been established by biopsy.

The differential diagnosis of DAH is listed in [Box 46.2](#). Although some of these diseases have no specific therapy, establishing a diagnosis and instituting supportive care help to avoid unnecessary diagnostic and therapeutic maneuvers. Many of the vasculitides are stabilized only with aggressive immunosuppressive therapy, which would not be appropriate for infectious diseases that can present with the same features in a chest radiograph.

Bronchoscopy with transbronchial biopsy and bronchoalveolar lavage (BAL) are usually performed in a patient with unknown pulmonary infiltrates in the intensive care unit (ICU) if respiratory compromise is not severe. Although often not sufficient to establish a specific diagnosis, finding a bloody lavage, hemosiderin-laden macrophages, and the lack of specific pathogens can presumptively yield a diagnosis of DAH. The diagnosis of DAH is best made by quantitation of hemosiderin in alveolar macrophages obtained by BAL. A Prussian blue stain is graded by the methods of Kahn and colleagues⁶⁰; hemosiderin scores above 100 are virtually diagnostic of alveolar hemorrhage. Hemosiderin-laden macrophages may not appear in BAL fluid until 48 to 72 hours after acute hemorrhage, resulting in a low sensitivity for hemosiderin scores in this setting.⁶¹

Box 46.2 Causes of Diffuse Alveolar Hemorrhage**Immunologic Diseases**

Anti-glomerular basement membrane antibody disease (Goodpasture's syndrome)
 Vasculitides associated with circulating or in situ immune complexes
 Systemic lupus erythematosus
 Mixed connective tissue disease
 Schönlein-Henoch purpura
 Essential mixed cryoglobulinemia
 Tumor-related vasculitis
 Endocarditis-related vasculitis
 Polyarteritis nodosa
 Systemic necrotizing vasculitis
 Vasculitides associated with antineutrophil cytoplasmic antibodies
 Wegener's granulomatosis
 Microscopic polyangiitis
 Idiopathic necrotizing crescentic glomerulonephritis
 Rapidly progressive glomerulonephritis
 Associated with other connective tissue diseases, pathophysiology unknown
 Rheumatoid arthritis
 Progressive systemic sclerosis
 Behçet's disease
 Associated with other renal diseases
 IgA nephropathy
 Diabetic nephropathy
 Associated with precipitating antibodies to milk (Heiner's syndrome)
 Idiopathic pulmonary hemosiderosis
 Primary antiphospholipid antibody syndrome

Chemical or Drug-Related Causes

Amiodarone
 D-Penicillamine
 Isocyanates
 Nitrofurantoin
 Retinoic acid
 Trimellitic anhydride
 "Crack" cocaine
 Sirolimus
 Everolimus

Propylthiouracil-induced vasculitis
 Erlotinib
 Bevacizumab
 Gemcitabine
 Infliximab

Transplant-Related Causes

Bone marrow transplant
 Renal transplant
 Lung transplant

Bleeding Diathesis

Thrombocytopenia
 Leukemia with diffuse alveolar damage
 Viral pneumonia
 Bacterial or fungal sepsis
 Radiation
 Chemotherapy toxic to lung
 Blast counts >80,000/ μ L
 Extrinsic anticoagulants/thrombolytics
 Warfarin overdose
 Tissue plasminogen activator
 Platelet glycoprotein IIb/IIIa inhibitors
 Coagulopathies
 Cirrhosis
 DIC

Infections

Legionnaires' disease

Pulmonary Venous Hypertension

Mitral stenosis
 Mitral regurgitation
 Pulmonary capillary hemangiomatosis
 Pulmonary veno-occlusive disease
 Fibrosing mediastinitis
 Congenital heart disease

Diffuse Lung Injury

Negative-pressure pulmonary hemorrhage
 Breath-hold diving
 Postictal neurogenic pulmonary edema

DIC, disseminated intravascular coagulation; IgA, immunoglobulin A.

IMMUNOLOGIC LUNG DISEASE

The differential diagnosis of DAH is narrowed significantly if renal abnormalities are present. Although pulmonary-renal syndromes can often be stabilized with high-dose corticosteroids alone pending further evaluation, directed therapy depends on the measurement of specific autoantibodies and evaluation of a renal biopsy. Alveolar hemorrhage is a hallmark of anti-glomerular basement membrane (GBM) antibody disease (Goodpasture's disease). This disease is 75% male-predominant and follows a flulike prodrome in 30% of patients. Pulmonary hemorrhage is the initial manifestation in 90%, and an abnormal urinalysis is found in 80%. An iron-deficiency anemia from sequestration of iron within pulmonary alveolar macrophages is commonly associated with the disease. The IgG antibodies reacting to a component of type IV collagen are found in

linear deposits on the basement membrane of both alveoli and glomeruli and are circulating in 90% of cases.⁶² In the appropriate clinical setting, the presence of circulating anti-GBM antibodies is sufficient to make a diagnosis without biopsy and institute plasmapheresis with or without plasma exchange for severe pulmonary or renal disease. After initial stabilization, corticosteroids and immunosuppressive medications will usually prevent further antibody production. Treatment with rituximab is also an option for patients intolerant of or refractory to standard therapy.⁶³

Steroids alone are usually sufficient to treat alveolar hemorrhage associated with the immune complex vasculitides. These disorders are usually associated with hypocomplementemia and an elevated titer of antinuclear antibody. Systemic lupus erythematosus (SLE) is the most frequent of the immune complex disorders causing alveolar

hemorrhage. SLE rarely presents with alveolar hemorrhage without other manifestations of active disease. Although the alveolar hemorrhage of SLE usually occurs from acute lupus pneumonitis, the high incidence of pneumonia, congestive heart failure, and aspiration in these patients makes a presumptive diagnosis problematic. Lupus pneumonitis usually stabilizes on 1 to 1.5 mg/kg/day methylprednisolone.

DAH also complicates other connective tissue diseases and systemic vasculitides with or without immune complex deposition. Mixed connective tissue disease, cryoglobulinemia, polyarteritis nodosa, progressive systemic sclerosis, rheumatoid arthritis, Behçet's disease, endocarditis and tumor-related vasculitis, Schönlein-Henoch purpura, and systemic necrotizing vasculitis have all been described in association with DAH. Specific diagnosis depends on the nonpulmonary features of disease presentation.

Alveolar hemorrhage is an unusual manifestation of Wegener's granulomatosis.⁶⁴ The classic triad of renal dysfunction, upper airway disease, and pulmonary infiltrates is present in less than 20% of patients at presentation; however, pulmonary infiltrates are present in 45%.⁶⁵ The pulmonary findings are characterized by nodules that may cavitate, lobar infiltrates that are often transient, upper airway obstruction from the granulomatous inflammation that follows airway ulceration, prominent interstitial markings with or without hilar and mediastinal adenopathy, or alveolar hemorrhage. Antineutrophil antibodies against proteinase 3 in cytoplasmic granules (c-ANCA) are found in the serum of 85% to 90% of patients with active Wegener's granulomatosis and are 97% specific for the diagnosis.⁶⁶

Among the many causes of rapidly progressive crescentic glomerulonephritis (RPGN) are small-vessel vasculitides such as microscopic polyangiitis that are associated with pulmonary hemorrhage in a third of patients.⁶⁷ Therapy of these vasculitides and Wegener's granulomatosis usually includes corticosteroids and immunosuppressive therapy. In patients with life-threatening respiratory failure, extracorporeal membrane oxygenation (ECMO) has proved lifesaving in patients with ANCA-positive vasculitides and SLE awaiting onset of systemic therapy.^{68,69} Use of recombinant factor VIIa has also been reported in this setting.^{70,71}

IDIOPATHIC PULMONARY HEMOSIDEROSIS

Idiopathic pulmonary hemosiderosis is characterized by repetitive episodes of hemorrhage that occur without obvious precipitating factors. Open lung biopsy fails to demonstrate immune complexes, and no other organ system is affected. Therapy with corticosteroids and occasionally cyclophosphamide has been attempted, although no controlled trials have been performed.

IMMUNOCOMPROMISED HOST

DAH complicates autologous and allogeneic bone marrow transplantation in up to 21% of cases.^{72,73} Risk factors include age younger than 40 years, the presence of underlying solid tumors, renal insufficiency, and severe mucositis. The typical presentation is characterized by onset near the time of leukocyte recovery and is heralded by high fever and diffuse pulmonary infiltrates that prompt BAL. Typically the lavage fluid appears progressively bloody over serial aliquots, and no pathogenic organisms are recovered on bacterial, fungal, or viral culture. Mortality rate has been reported from 80%

to 100% despite aggressive supportive care^{72,74} but may be improved with corticosteroid therapy.⁷⁵ The optimal dosage and duration of corticosteroid treatment remain controversial, but standard regimens include 1 g/day methylprednisolone administered for 3 days and thereafter tapered over 2 months.⁷⁵ The use of recombinant factor VIIa in patients with life-threatening DAH refractory to steroids has been reported.⁷¹ More recent reports reveal a favorable prognosis in patients with early (first 30 days) versus late DAH and autologous versus allogeneic transplants with an overall mortality rate of 48%.⁷³

A similar syndrome characterized by fever and pulmonary infiltrates has been noted in 5% of transplant patients, but hemoptysis is rare. Pulmonary capillaritis following lung transplant also can result in DAH. Hemoptysis is seen in up to 25% of cases, with fulminant respiratory failure seen in 18%.⁷⁶ This form of acute allograft rejection appears less responsive to corticosteroid therapy than acute lung rejection but has a more favorable response to plasmapheresis. No long-term adverse effects on allograft function are apparent.

BLEEDING DIATHESIS

Although hemoptysis may occur with intrinsic coagulopathies, extrinsic anticoagulants and antiplatelet agents, thrombocytopenia, and fibrinolytics, patients at risk should undergo bronchoscopy to exclude other lesions such as neoplasm. Usually, the disorders of hemostasis are not in themselves solely responsible for hemoptysis, and bleeding can usually be ascribed to the combined presence of another cause, often as insignificant as an upper respiratory infection.

Leukemia patients may be particularly susceptible to DAH when chemotherapy-induced thrombocytopenia is combined with diffuse alveolar damage from other causes. Viral infections, sepsis, radiation, chemotherapy agents with pulmonary toxicity, and leukostasis from blast counts exceeding 80,000 cells/mm³ may all produce diffuse alveolar damage in leukemia.⁷⁷ Therapy is directed toward correction of thrombocytopenia and supportive care of lung injury.

DRUG-INDUCED ALVEOLAR HEMORRHAGE

Hemoptysis due to drug-induced alveolar hemorrhage is rare and may result from therapeutic medications, illicit drugs, and other agents. Implicated agents include crack cocaine,⁷⁸ amiodarone,⁷⁹ nitrofurantoin,⁸⁰ D-penicillamine,⁸¹ retinoic acid,⁸² propylthiouracil,⁸³ infliximab,⁸⁴ inhaled resins containing trimellitic anhydride,⁸⁵ and various chemotherapeutic agents.⁸⁶⁻⁸⁹

VASCULAR ABNORMALITIES

Almost all blood vessels that course through the thoracic cavity have been associated with fistula formation to an airway with resultant hemoptysis. Often this occurs in the setting of endovascular infection, inflammation, congenital or acquired stenoses, aneurysms of these vessels, or chest surgery. Some of the rare vascular-to-airway fistulas that have been described include (1) carotid artery to trachea in a patient with occult laryngeal cancer⁹⁰; (2) various abdominal arterial supplies to pulmonary sequestrations⁹¹; (3)

syphilitic aneurysms of the ascending aorta and other thoracic arteries to pulmonary parenchyma⁹²; (4) coronary artery bypass grafts to pulmonary parenchyma or bronchial artery^{93,94}; (5) splenopulmonary shunt in portal hypertension following splenectomy⁹⁵; (6) left ventricular pseudoaneurysms⁹⁶ to pulmonary parenchyma; and (7) vena caval-bronchial fistulas.⁹⁷ Several of the more common bronchovascular communications deserve comment.

AORTOBRONCHIAL FISTULAS

Dissecting aortic aneurysms are often of subacute or chronic duration with variable degrees of inflammation around the dissection. As an aneurysm enlarges it may cause lung compression, pleural adhesions, and dissection of blood into the pulmonary parenchyma. Particularly in situations in which an aortic graft has been previously placed, aortic graft infection may also be present. The net result is an often stuttering course of hemoptysis marked by sudden large bleeds. Therapy is surgical, although these operations are difficult in the presence of graft infections and prior operations.

PULMONARY ARTERY ANEURYSMS

Aneurysms of the pulmonary artery remain rare causes of hemoptysis.⁹⁸ Mycotic aneurysms are commonly caused by *Mycobacterium tuberculosis*, syphilis, *S. aureus*, and streptococcal species. Poststenotic dilation may occur in congenital pulmonary artery strictures. Structural vascular abnormalities such as those found in Marfan syndrome can also affect the pulmonary arteries.

Behçet's disease, characterized by oral ulcers, uveitis, arthritis, and cutaneous vasculitis, is the only common large-vessel vasculitis that affects the pulmonary arteries.⁹⁹ These multiple aneurysms may resolve with high-dose corticosteroid therapy or cyclophosphamide.^{100,101}

An idiopathic syndrome characterized by fatal hemoptysis from pulmonary artery aneurysms, associated with fever and recurrent superficial and deep venous thromboembolism, was originally reported in 1959 by Hughes and Stovin.¹⁰² Although infection and angiodysplasia have been proposed as possible causes of the aneurysms, the current consensus is that vasculitis is the primary process.¹⁰³

ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVMs) present with progressive hypoxemia, paradoxical emboli, or bleeding complications including hemoptysis or hemothorax.¹⁰⁴ Although the majority of these lesions are likely congenital telangiectasias that enlarged over years,¹⁰⁵ acquired arteriovenous malformations (AVMs) have been noted after chest surgery and trauma and have been associated with actinomycosis, schistosomiasis, cirrhosis, and metastatic carcinoma.¹⁰⁶ The hereditary Osler-Weber-Rendu disease (OWR) is associated with hemorrhagic telangiectasias in many organ systems. Approximately 15% of OWR patients have pulmonary arteriovenous aneurysms,¹⁰⁷ and up to 36% of patients with a single PAVM and 57% of patients with multiple PAVMs have OWR.¹⁰⁸ Bronchial artery telangiectasias with bleeding¹⁰⁹ have also been described, although the pathogenic relationship to pulmonary artery telangiectasias remains speculative. Treatment of PAVMs, particularly if hemoptysis has developed, is to obliterate the lesion with BAE.¹¹⁰

TRAUMA

Hemoptysis following major trauma requires emergent thoracic surgical consultation and management. Although some cases will be simple lung contusions that manifest as a focal radiographic abnormality on chest radiograph with blood-streaked sputum present, approximately 15% of thoracic trauma victims with hemoptysis need early exploration. The majority of cases with hemoptysis need bronchoscopy to localize bleeding and exclude a tracheobronchial rupture, which can be clinically silent for weeks. The most common reason for emergent thoracotomy remains pulmonary hemorrhage. Pneumonorrhaphy (suture repair of the lung) is preferred for minor injuries; lobectomy and pneumonectomy, performed for more severe injuries, carry mortality rates of 55% and 89%, respectively.¹¹¹

Lung laceration is common after penetrating pulmonary injury. However, it can also occur after blunt thoracic trauma in which sheer forces of acceleration or deceleration leave intraparenchymal lacerations involving airways or vasculature. Continued bleeding into the lung can present with rupture into the pleural space (hemothorax), intraparenchymal hematoma formation, or hemoptysis. Thoracic splenosis is a rare and remote event from the time of trauma. In this condition, splenic tissue is transported across the diaphragm after penetrating injury, where it becomes functional and vascularized within the lung. Hemoptysis may thereafter occur spontaneously.

VASCULAR MONITORING CATHETERS

Use of pulmonary artery catheters has decreased significantly and complications causing hemoptysis occur rarely. Pulmonary artery catheters should be inflated in the proximal pulmonary circulation for 20 seconds or less to obtain pulmonary artery occlusion pressures. More distal and prolonged inflation can cause fatal pulmonary artery dissection, pseudoaneurysm formation, or pulmonary artery rupture.^{112,113} Endovascular damage may predispose to thrombus formation and pulmonary infarction. Preventive measures include placement of the catheter at an insertion distance when full inflation is required to obtain an occlusion pressure, slowly inflating the balloon (never inflating against resistance), full inflation of the balloon to prevent the catheter tip from projecting beyond the balloon, and daily monitoring of catheter position with chest radiography.

If hemoptysis occurs with a pulmonary artery catheter in place, rapid diagnosis and treatment are required. Risk factors for pulmonary artery rupture include concomitant anticoagulation, cardiopulmonary bypass, balloon migration, hypothermia, advanced age, and pulmonary hypertension.¹¹³ Surgical resection of the involved lobe or angiographic ablation of the involved pulmonary artery has been successful in decreasing the incidence of recurrent and often fatal hemoptysis. Other successful interventions for acute conditions have included proximal reinflation of the pulmonary artery catheter to stop blood flow to the pulmonary artery segment that is bleeding; high levels (18 mm Hg) of positive end-expiratory pressure to decrease the pulmonary artery to bronchial pressure gradient; resumption of

cardiopulmonary bypass for patients in cardiac surgery; and operative banding of the pulmonary artery, which can be unclamped 48 hours later.^{113,114}

MANAGEMENT

The primary principles of managing massive hemoptysis are airway and lung protection, localization of the bleeding source, and control of hemorrhage. Assessments and interventions are frequently performed empirically because the cause of hemoptysis may not be known at the time of presentation. Therapy to control minor and moderate hemoptysis can usually proceed along diagnostic paths. The inability to determine when and whether an individual patient's hemoptysis will worsen suggests that all patients with an estimated blood loss of more than 200 mL should be hospitalized in a unit in which airway support can be rapidly provided if necessary.

Massive hemoptysis should be managed within a framework of expeditious therapy to stabilize and resuscitate the patient. [Figure 46.1](#) is a suggested algorithm for management. A multidisciplinary collaborative approach involving intensivists, pulmonologists, interventional radiologists, and thoracic surgeons is optimal to improve outcomes.⁷ The urgency and aggressiveness of management are influenced by the rate of bleeding. The study by Crocco and colleagues⁶ ([Table 46.1](#)) demonstrated that the incidence of death was 71% in patients with 600 mL of hemoptysis in less than 4 hours, compared with 22% and 5% mortality rate if 600 mL of hemoptysis occurred in 4 to 16 hours and 16 to 48 hours, respectively. Sputum containers should be placed at the bedside of patients who are not intubated to allow measurement of blood loss and an estimate of the bleeding rate. High bleeding rates, hemodynamic instability, and severe oxygenation failure signal the need for rapid evaluation and treatment. A critical care setting is optimal for patients with massive hemoptysis.

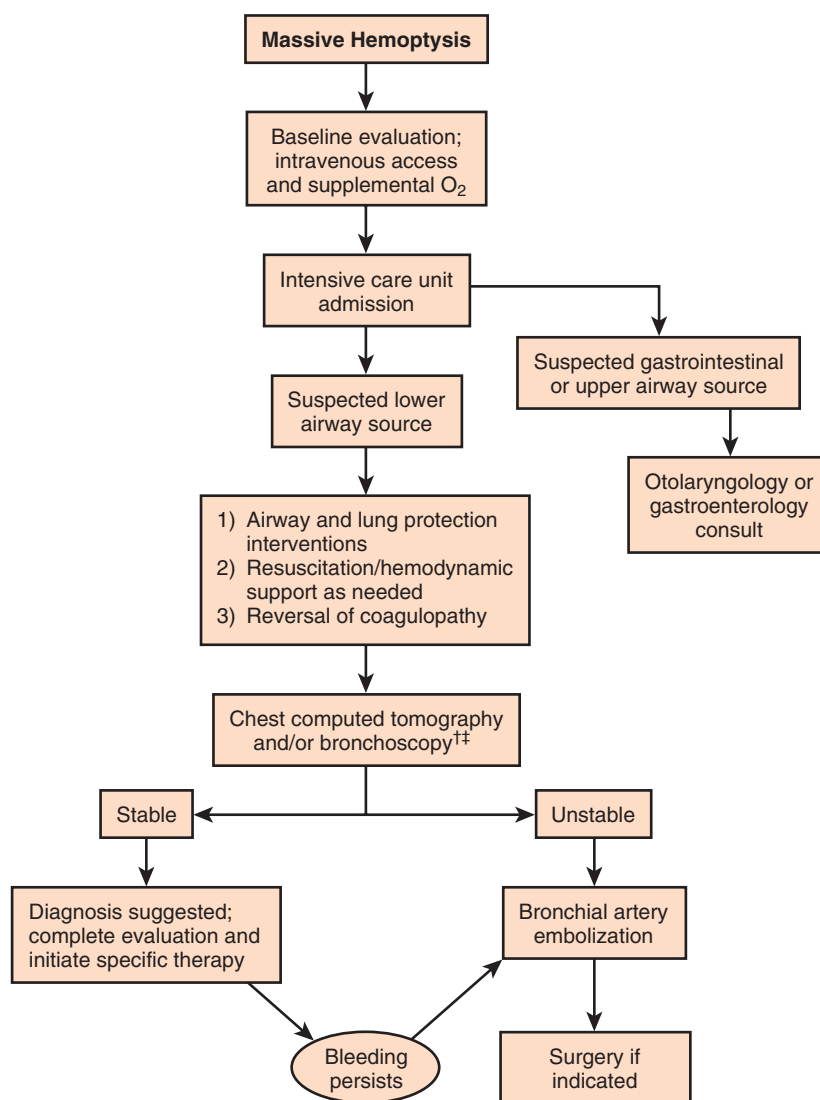

Figure 46.1 Massive hemoptysis. *History and physical examination, complete blood count, coagulation studies, type and cross-match, chest radiograph, arterial blood gas. [†]Local availability and patient stability should guide choice; computed tomography preferred in initial evaluation in stable patient. [‡]Local measures including topical vasoconstrictors, bronchial blockers, laser photocoagulation, electrocautery, and hemostatic agents can be used endobronchially.

Table 46.1 Mortality Associated with Rate of Bleeding

Blood Loss	Operable				Nonoperable	
	Surgical Management		No Surgery			
	No. of Patients	Deaths	No. of Patients	Deaths	No. of Patients	Deaths
600 mL in <4 hr	11	4 (36%)	6	6 (100%)	11	10 (91%)
600 mL/4-16 hr	10	1 (10%)	3	1 (33%)	5	2 (40%)
600 mL/16-48 hr	11	1 (9%)	0	0	10	0

In addition to the management steps outlined later, laboratory studies should be obtained, including complete blood count, coagulation studies, and type and cross-match for possible blood transfusion. An arterial blood gas measurement may be needed to assess ventilation and acid-base status, although pulse oximetry is usually adequate to assess oxygenation. Additional studies may be needed to investigate possible causes of hemoptysis such as infection or vasculitis. The hemodynamic status of the patient should be evaluated and fluids or blood administered for hypotension or evidence of impaired oxygen delivery. Antibiotics may be indicated if there is suspicion of active infection.

AIRWAY AND LUNG PROTECTION

Patency of the airway and the ability to protect the airway should be assessed as soon as hemoptysis is noted. All patients should be provided with supplemental oxygen as needed to maintain adequate oxyhemoglobin saturation. Patients with mild to moderate amounts of hemoptysis usually do not require intubation but intubation in massive hemoptysis is usually needed to facilitate diagnostic and therapeutic interventions as well as to provide support for oxygenation and ventilation. Additional steps may be needed to prevent contamination of the unaffected lung from blood and to preserve respiratory function.

PATIENT POSITIONING

If the source of bleeding is localized to one lung, the patient with massive bleeding should be positioned with the bleeding side down to keep bleeding contained to one lung. Once the airway is secured, the optimal patient position is more controversial. Clotting of blood in a dependent lung has the potential to tamponade the bleeding, yet clotted blood in the proximal airway can result in lung collapse and atelectasis. Furthermore, if the pulmonary circulation is bleeding, it can be influenced by gravity by placing the bleeding segment higher than other areas of the chest. By converting that segment to a zone 1 condition in which alveolar pressure is higher than pulmonary artery pressure, bleeding may be decreased.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is often difficult in patients with active bleeding. Orotracheal intubation is preferred to allow use of a larger endotracheal tube (preferably 8 mm inner diameter or larger) in order to facilitate suctioning, ventilation, and bronchoscopy. The orotracheal route also allows for selective mainstem bronchial intubation if needed.

If the patient's physical examination, chest radiograph, and other imaging studies readily identify the bleeding

lung, specific interventions to protect the airway to the normal lung can be attempted. Mechanisms to localize ventilation to one lung using a single-lumen endotracheal tube include selective intubation of one of the mainstem bronchi and selective endobronchial tamponade with a bronchial blocker (see later discussion).

Selective bronchial intubation is easiest in a patient with a bleeding left lung. Because of the leftward displacement of the carina in most individuals, an endotracheal tube advanced blindly will almost always intubate the right main bronchus. Unfortunately, the right upper lobe bronchus is so close to the carina that a right mainstem intubation may also cause right upper lobe atelectasis. The ability to ventilate and oxygenate a patient with the right lower and right middle lobes alone depends on the underlying cardiopulmonary reserve. Intubation of the left main bronchus is facilitated by placing the patient in a right lateral decubitus position to shift the mediastinum rightward. Angulation of the endotracheal tube curvature toward the left and progression of the tube over a coudé catheter may be helpful. Selective mainstem intubations can be facilitated by a bronchoscope.

DOUBLE-LUMEN ENDOTRACHEAL TUBES

Devices utilized for single-lung ventilation have also been applied to the management of hemoptysis.¹¹⁵ A double-lumen endotracheal tube is an alternative to a single-lumen endotracheal tube for airway management in massive hemoptysis. Successful placement of this type of endotracheal tube requires training and experience.¹¹⁶ The independent isolation of each mainstem bronchus allows for single-lung ventilation and isolation of the unaffected lung from blood contamination when bleeding is localized to one lung. The smaller suction ports of each independent lumen can cause difficulty in suctioning blood. Endobronchial evaluation requires a pediatric bronchoscope or double-lumen tube removal once bleeding has been controlled. Proximal airway masses may preclude placement of a double-lumen endotracheal tube.

LOCALIZATION OF BLEEDING

Localization of bleeding facilitates diagnostic and therapeutic efforts regardless of the amount of hemoptysis. Because blood in the mouth can originate from the gastrointestinal tract or from diverse sites in the sinuses, nasal airway, or upper airway proximal to the larynx, an initial evaluation is needed to confirm that bleeding is from the lung. One series of hemoptysis patients found an upper airway source of bleeding in 10%.¹¹⁷ The characteristics of the expectorated blood and clinical presentation of the patient often

Table 46.2 Features of Hemoptysis and Patient Presentation

Hemoptysis Feature	Clinical Presentation
Blood usually bright red	Often dyspneic
Portion of blood usually frothy	Hypoxemia
Alkaline pH	
Blood usually mixed with sputum	Preceding cough common
Alveolar macrophages may be present in sputum smear	Anemia and melena uncommon

help in differentiating hemoptysis from upper airway or gastrointestinal sources (Table 46.2). A pH assessment of the blood (low pH expected in gastric hemorrhage) and observation of expectorated sputum can be performed at the bedside.

CHEST RADIOGRAPH

All patients with hemoptysis need a baseline evaluation that consists of a physical examination and chest radiograph. The chest radiograph may suggest specific diagnoses and help in localization of bleeding. However, blood filling the alveoli can obscure an underlying pulmonary pathologic condition and present with bilateral infiltrates, making localization of the bleeding site problematic.

CHEST COMPUTED TOMOGRAPHY

The importance of chest CT in the diagnosis of acute hemoptysis and localization of bleeding has increased with advances in technology. In a series of 80 patients with massive hemoptysis, emergency high-resolution computed tomography (HRCT) was not only equivalent to bronchoscopy in localizing bleeding (70% vs. 73%), but it was more efficient than bronchoscopy for identifying the cause of bleeding (77% vs. 8%). Findings on HRCT also directly affected treatment in more than 30% of patients in this study.¹¹⁸ HRCT also allows the adequate prediction of non-bronchial systemic arterial supply, which can be the cause of bleeding in massive hemoptysis and a significant cause of recurrent bleeding after successful BAE.¹¹⁹ Contrast enhancement increases the yield by identifying vascular abnormalities (i.e., thoracic aneurysm or AVMs) that would allow for more timely surgical referral.

Use of multidetector CT angiography to visualize the bronchial and nonbronchial systemic vasculature has been found to increase the number of pulmonary artery vaso-occlusions and reduce the number of urgent surgical resections compared to single-detector helical CT.¹²⁰ In CF patients with massive hemoptysis, electrocardiographically synchronized, prospectively triggered multidetector CT angiography of the aorta accurately predicted the location of ectopic bronchial arteries. The use of this technique was felt to decrease the BAE radiation dose and contrast volume and likely reduced table time compared to a conventional complete aortogram.¹²¹

CT modalities including multiplanar reconstruction and endobronchial simulation (i.e., virtual bronchoscopy) will likely increase the diagnostic yield of chest CT even further as these techniques become more available. Chest CT,

except in unstable patients, should therefore be performed in patients prior to bronchoscopy and BAE to efficiently guide management.

BRONCHOSCOPY

Although the diagnostic yield of bronchoscopy remains low in hemoptysis due to causes other than endobronchial carcinoma, it remains a vital tool in the management of acute massive hemoptysis in unstable patients. Localization of bleeding can facilitate immediate interventions for hemorrhage control including appropriate patient positioning, selective intubation, endobronchial tamponade, endobronchial infusions, laser photocoagulation, and guidance for BAE or surgical resection. Recent studies, however, have suggested that patients with lateralizing radiography and known causation who are candidates for BAE do not need prior bronchoscopy unless bronchoscopic airway management is necessary.^{20,122,123} This strategy can avoid delays in definitive therapy, reduce cost, and avoid the risk of airway compromise from sedation associated with bronchoscopy.

During massive hemoptysis the rigid bronchoscope has some advantages over flexible fiberoptic instruments. Ventilation is secured through the bronchoscope lumen, suctioning is not impeded, and visualization is less likely to be significantly impaired. The flexible instrument has advantages of subsegmental localization of bleeding and visualization of the upper lobes. Because the two bronchoscopes have complementary properties, they are often used together. The rigid bronchoscope is used to secure ventilation and localize the bleeding lung; the flexible scope passed through the rigid scope allows for further definition of the bleeding site and diagnosis.

HEMORRHAGE CONTROL

EXPECTANT THERAPY

Cough suppression has been recommended for the majority of patients with massive hemoptysis with moderate doses of codeine being most commonly used. Although no prospective study has evaluated the efficacy of cough suppression on patient outcome, the large swings in intrathoracic pressure that occur with coughing are likely to be detrimental.

The additional factor that must be considered in cough suppression is the necessary removal of blood clots that can cause endobronchial obstruction. Particularly when a central airway lesion is responsible for bleeding, the suctioning necessary to remove blood clots may be associated with rebleeding and perpetuation of a vicious cycle. Blood clots left unsuctioned, however, may cause atelectasis, which is detrimental to patient weaning from the ventilator. Although endobronchial streptokinase (1000 IU/mL; total dose 30,000 to 80,000 IU) has been used for dissolution of central blood clots,¹²⁴ airway stabilization can usually be obtained with serial bronchoscopies and suctioning alone.

ENDOBONCHIAL TAMPONADE

Acute lung bleeding may be amenable to control by endobronchial tamponade with balloon-tipped devices known as bronchial blockers.¹²⁵⁻¹²⁸ Several types of devices are available: Fogarty vascular embolectomy catheter, a single-lumen endotracheal tube with an enclosed moveable bronchial blocker, and a wire-guided bronchial blocker.¹²⁹ Regardless

of the selected device, experience is required for successful placement and safe utilization.¹¹⁶ The blocker is directed to the bleeding bronchus under guidance of fiberoptic bronchoscopy. By advancing the blocker to the smallest subsegment to which bleeding can be visualized, bleeding can be contained and diagnostic workup can continue. Other balloon catheters can also be used for this purpose,¹³⁰ although they must be carried to the bleeding site on the outside of the bronchoscope by the bronchoscopic shuttle technique.¹³¹ Multiple catheters can be placed if hemoptysis is multifocal and catheters can be left in place for 24 to 48 hours until bleeding is controlled.¹²⁸

ENDOBONCHIAL INFUSIONS

Although a variety of agents have been infused into the airway through the bronchoscope to control bleeding, no studies directly compare the agents with each other or with other modalities of therapy. Nevertheless, the potential advantage of these agents is their administration during bronchoscopy for localization of bleeding. Thrombin and fibrinogen-thrombin mixtures have been used in some sites to provide a hemostatic clot in the area of bleeding with good success.^{132,133} Commercial fibrinogen is not available in the United States for patient use. Oxidized regenerated cellulose mesh, a biodegradable cellulose fabric, is an alternative procoagulant used in patients with massive hemoptysis and showed a 98% success rate in a series of 57 patients.¹³⁴ Once deployed in the area of hemorrhage, it absorbs blood, swelling into a gelatinous mass that promotes tamponade and coagulation. Endobronchial sealing with *n*-butyl cyanoacrylate, a biocompatible glue with prothrombotic properties, has also been used with success in small case series.¹³⁵

Topical vasoconstrictors including iced saline,¹³⁶ epinephrine,¹³⁷ and vasopressin or vasopressin derivatives^{138,139} have also been used effectively for airway bleeding in anecdotal reports. The likely mechanism is vasoconstriction of bronchial arteries. These may be a safe, effective alternative in patients without access to BAE or surgery, or in unstable patients in need of a temporizing intervention until definitive therapy is available.

LASER PHOTOCOAGULATION

The neodymium:yttrium aluminum garnet (Nd:YAG) or argon plasma laser has been used successfully for airway carcinoma with persistent hemoptysis. Recognizing that carcinomatous bleeding is usually progressive and can be life threatening, aggressive photocoagulation of the endobronchial site may provide the only possibility for palliation after chemotherapy and radiation have been exhausted. Success has been reported in approximately 60% of cancer patients with hemoptysis.¹⁴⁰ Appropriate training, however, is imperative to ensure appropriate patient selection and to avoid catastrophic complications such as tracheal fire or vessel perforation.¹⁴¹

BRONCHIAL ARTERY EMBOLIZATION

Bronchial artery embolization (BAE) was first described in 1974 to control massive hemoptysis in the nonsurgical patient.¹⁴² Subsequent studies on safety and efficacy have confirmed immediate, safe control of hemoptysis in 79% to 100% of a variety of patients, resulting in early use of BAE in the management strategy.¹⁴³⁻¹⁵¹ The technique for BAE

localizes the bronchial arteries supplying the lobe that is bleeding. A formal bronchial arteriogram is performed to ensure that there is no communication to the anterior spinal artery, to determine whether a vascular pathologic condition is present, and to ensure that the bleeding area of lung parenchyma is served by the vessel. Only rarely will vascular extravasation indicative of bleeding be observed, usually in massively bleeding patients. Angiographic signs that suggest a source of bleeding include hypertrophied/enlarged/tortuous bronchial arteries with parenchymal hypervascularity, bronchial artery aneurysms, and bronchial artery to pulmonary vein or pulmonary artery shunting.¹⁵² Angiographic technique usually begins with injection of contrast agent in the descending aorta just below the left subclavian artery to identify bronchial arteries supplying the majority of the lung and phrenic arteries supplying the lung bases. Identification of anomalous origins of the bronchial arteries may require a full arch aortogram in some patients.¹⁵³ For pathologic conditions of the lower lung, a selective phrenic artery injection is used if the entire lung is not visualized by bronchial injections. Rarely, these lower injections may demonstrate a pulmonary sequestration. For pathologic conditions of the upper lung zone, a unilateral subclavian artery injection is done to exclude nonbronchial systemic collateral arteries.

No studies have evaluated the optimal embolization material for control of hemoptysis. Gelatin sponge particles, polyvinyl alcohol particles, or liquid polymers (e.g., *n*-butyl cyanoacrylate) with a predetermined polymerization time have all been used with success.¹⁵⁴ Velour, polyurethane particles of varying size, metal coils, protein macroaggregates, and fibrinogen-thrombin mixtures¹⁵⁵ have also been instilled. Combinations of materials are used in a significant number of patients.^{150,156} Liquid sclerosants, such as absolute alcohol or Gelfoam powder, should be used with caution because they may pass into the smallest vessels at the bronchial surface, producing bronchial necrosis.¹⁵⁷

Significant complications of BAE are rare when appropriate technique is employed. Chest pain, dysphagia, and fever are the most common complications. The most devastating complication is spinal cord infarction resulting from embolization of the anterior spinal artery, which arises from the bronchial artery circulation in approximately 5% of normal patients. However, with proliferation of the bronchial artery circulation, as occurs in CF, communication to the anterior spinal artery may be found in up to 55% of cases.¹⁵⁸ By performing high-quality bronchial arteriograms to define vascular anatomy and avoiding the anterior spinal artery by wedging the angiography catheter distal to its takeoff (or by avoiding the vessel altogether), a safe procedure can almost always be ensured. The recent introduction of microcatheter technology (i.e., "superselective" catheterization) allows achievement of a more distal, safe catheter position and has greatly reduced the number of aborted procedures and complications arising from anterior spinal artery embolization.

Recurrent hemoptysis is common after BAE and can occur immediately, in the first several weeks to months (early), or after several years (late). Immediate recurrence of hemoptysis in the first few days after BAE may occur in approximately 10% of patients¹⁴⁴ and may be due to several causes. For the patient who continues to bleed during the

procedure, the appropriate blood vessel usually has not been embolized. Other common causes include bleeding from nonbronchial systemic or pulmonary vessels, particularly if not evaluated initially, and lysis of the hemostatic plug in the embolized bronchial artery. Recurrence of hemoptysis in the first several months after BAE may be related to incomplete embolization, although later recurrence at 1 to 2 years may be related to neovascularization or recanalization related to inflammation or disease progression.¹⁵⁹ Reporting of outcomes varies considerably in BAE studies but early recurrence of bleeding may occur in 3.5% to 26% of patients.^{145,147,149,150} Late recurrence of bleeding may occur in 10% to 40% of patients.^{143,145,146,149,150} The incidence of recurrence is not uniform in all lung diseases, and higher recurrence rates are noted in *Aspergillus* fungus balls, bronchiectasis, tuberculosis, and lung cancers.* Use of superselective embolization, which provides less of a stimulus for neovascularization, may improve recurrence rates.¹⁶¹ BAE can be considered a palliative intervention for the acute cessation of massive hemoptysis that allows for a more controlled evaluation of the patient for potentially curative interventions.

SURGERY

A significant question in control of massive hemoptysis is whether conservative management techniques including endobronchial tamponade and BAE are better than emergent surgery in improving outcomes. Given the high success rates of BAE and low associated morbidity and mortality rates, more conservative techniques are now considered first-line therapy over emergent surgery. The proportion of patients with massive hemoptysis who undergo emergent or urgent surgery often is not reported, but recent studies found 12% to 14% of patients required surgical intervention.^{151,162} Although perioperative and hospital mortality rates were high in past experience, more recent studies report a mortality rate of less than 15%.¹⁶²⁻¹⁶⁵ The outcome of surgery is likely influenced by the cause and severity of hemoptysis, patient comorbid conditions, extent of lung resection, and experience of the surgical team. Absolute indications for surgery do not exist, but patients with vascular disruptions (e.g., leaking aortic aneurysm, AVMs, pulmonary artery rupture, chest trauma); focal fungal disease, tuberculosis, or bronchiectasis; or failed BAE or early recurrence of bleeding after BAE should be considered for urgent surgery in the setting of massive hemoptysis.^{148,160} Mycetomas, active tuberculosis, and bronchiectasis represent a large majority of the causes of hemoptysis in surgical reports.

Important issues in the assessment of a patient for thoracic surgery include the underlying cardiopulmonary reserve, precise localization of bleeding, and the focality of the patient's disease. Unfortunately, the safety of the large intrathoracic pressure swings involved with bedside spirometry in a massively bleeding patient has not been established. Because alveolarized blood can produce significant chest restriction on spirometry, a functional assessment is often obtained on the basis of premorbid exercise tolerance.

Patients with fibrosis and adhesions between the lung and chest wall, commonly seen in tuberculosis, fungal disease, and bronchiectasis, have significant surgical risks because they often require pneumonectomy. Physiologic lung exclusion, in which the bronchus and pulmonary artery of the involved lobe or lung are surgically interrupted, leaving the pulmonary veins intact, appears to be a viable alternative in such patients. In a series of 20 patients, Dhaliwal and colleagues¹⁶⁶ reported control of bleeding in all patients with no fatality and no significant morbidity. Video-assisted thoracoscopic procedures may be successful in some patients.¹⁶⁷

The decision regarding surgery for massive hemoptysis is a difficult one that often must be made rapidly, without all desired clinical information available. The availability of BAE and endobronchial tamponade may provide time for a reasoned decision to be made regarding surgery in all but the most rapidly bleeding patients.

OTHER THERAPIES

As new devices and interventions are developed for the management of other pulmonary and nonpulmonary conditions, some may be adapted to treat massive hemoptysis. Covered self-expanding stents have been used to occlude a bleeding site in a patient not treatable by BAE or surgery.^{168,169} Recombinant activated factor VII has been used to control hemoptysis in DAH^{70,170} and focal bleeding associated with community-acquired pneumonia,¹⁷¹ thoracic trauma,¹⁷² and CF.¹⁷³ Recombinant activated factor VII is not approved for use in hemoptysis, and clinicians must weigh adverse effects, thrombotic risk, and availability of other interventions when considering this treatment option.

KEY POINTS

- The adverse clinical effects of hemoptysis such as impaired gas exchange, airway obstruction, and hypotension are relevant for defining a life-threatening condition.
- Bleeding from the higher pressure bronchial circulation (rather than the pulmonary circulation) causes almost 90% of the cases of massive hemoptysis.
- Massive hemoptysis is more common with bronchiectasis, tuberculosis or its sequelae, lung cancer, and aspergilloma than with chronic bronchitis, pneumonia, and pulmonary emboli.
- DAH should be considered as a potential cause of hemoptysis in the presence of diffuse infiltrates on chest radiograph, systemic manifestations of vasculitis, hypoxemic respiratory failure, and anemia.
- The primary principles of managing massive hemoptysis are airway and lung protection, localization of the bleeding source, and control of hemorrhage.
- A multidisciplinary collaborative and organized approach to managing massive hemoptysis is needed to improve outcomes.

*See references 9, 143, 148-150, 159, 160.

KEY POINTS (Continued)

- Orotracheal intubation with a larger endotracheal tube (preferably 8-mm inner diameter or larger) is preferred for airway protection in massive hemoptysis to facilitate suctioning, ventilation, and bronchoscopy.
- Chest CT, except in unstable patients, should be performed in many patients prior to bronchoscopy and BAE to efficiently guide management.
- BAE is a safe and effective technique to control bleeding in massive hemoptysis and should be used as the initial therapeutic modality in most patients.
- Patients with vascular disease; focal fungal disease, tuberculosis, or bronchiectasis; or failed BAE or early recurrence of bleeding after BAE should be considered for urgent surgery of massive hemoptysis if they have sufficient cardiopulmonary reserve.

DEFINITION AND HISTORY

Pneumothorax is defined as air in the pleural space because of a break in the visceral or parietal pleura. The term *pneumothorax* was used for the first time in 1803.¹ Laennec² gave the first clinical description of pneumothorax in 1819; however, the first chest radiograph demonstrating this entity was not published until 1901.³ Definitive therapy became available with the advent of tube thoracostomy in 1876.⁴ It was thought to be always associated with tuberculosis until 1932 when “spontaneous pneumothorax in the apparently healthy” was first described.⁵

Spontaneous pneumothorax can be classified as primary or secondary. Primary spontaneous pneumothorax (PSP) occurs in patients with no apparent underlying lung disease. Secondary spontaneous pneumothorax (SSP) occurs in association with a known underlying lung disease such as

chronic obstructive pulmonary disease (COPD).⁶ Nonspontaneous causes of pneumothorax include traumatic and iatrogenic (Table 47.1).

INCIDENCE

The incidence of PSP in men varies geographically, from 7.4 per 100,000 population per year in the United States to 37 per 100,000 population per year in the United Kingdom. In women, the incidence is substantially less, ranging from 1.2 per 100,000 population per year in the United States to 15.4 per 100,000 population per year in the United Kingdom.⁷ The reason for these differences is not known. In a study that evaluated 1199 patients with pneumothorax that included 865 male patients and 334 female patients, 60.3% of the pneumothoraces were spontaneous, 33.6% were traumatic, and 6.1% were iatrogenic.⁸

The estimates of the incidence of recurrent PSP range from 20% to more than 50% with most recurrences occurring within the first year.⁹

Table 47.1 Classification of Pneumothorax

Type	Etiology
Primary spontaneous pneumothorax (PSP)	No underlying lung disease (but blebs/bullae commonly present)
Secondary spontaneous pneumothorax (SSP)	Associated with underlying lung disease (e.g., chronic obstructive pulmonary disease, cystic fibrosis, AIDS with emphysema)
Traumatic iatrogenic pneumothorax	Related to trauma to the thorax Secondary to transthoracic or transbronchial lung biopsy (10% risk), central venous catheterization, supraclavicular nerve block

From Grundy S, Bentley A, Tschopp JM: Primary spontaneous pneumothorax: A diffuse disease of the pleura. *Respiration* 2012;83:185-189.

PATHOPHYSIOLOGY

EMPHYSEMA-LIKE CHANGES

PSP occurs in patients with no previously known lung disease. It is important to note, however, that this does not mean there is no underlying pathologic process. A finding of abnormal pleura is very common in PSP if looked for carefully.¹⁰ Abnormalities seen in PSP are summarized in Table 47.2 and include blebs and bullae, which are otherwise known as emphysema-like changes (ELCs). These areas of weakness of the visceral pleura are prone to rupture, allowing air to leak into the pleural space. Abnormalities can be visualized radiographically with high-resolution computed tomography (CT) scans and macroscopically at thoracoscopy.^{10,11} High-resolution CT imaging reveals these defects in approximately 80% of PSP patients. The literature is mixed as to whether the presence of or extent of ELCs is directly related to the risk of recurrence. Some case series suggest that there is no association,^{12,13} although others suggest the presence of contralateral blebs/bullae is a risk factor for future pneumothorax.^{14,15} The only clear conclusion that can be drawn is that there is a direct association between the presence of ELCs and the occurrence (but not necessarily recurrence) of a pneumothorax (Table 47.2 and Fig. 47.1).

PLEURAL POROSITY

ELCs are not the sole cause of PSP. Air leak has been described in areas where no ELCs are seen, leading to the concept known as “pleural porosity.”^{16,17} When evaluated with fluorescein-enhanced autofluorescence, areas of high-grade abnormality in the visceral pleura were frequently visualized separate from any area of abnormality seen with white light at thoracoscopy in patients with PSP. High-grade abnormalities were not seen in control patients.¹⁸ Areas of

Table 47.2 Pathologic Changes Associated with Primary Spontaneous Pneumothorax (PSP)

Pathologic Abnormality	Description
Emphysema-like changes (ELCs) (i.e., blebs/bullae)	Macroscopically visible areas of weakness on visceral pleura Occasionally seen to be the site of air leak Present in approximately 80% of cases Often bilateral
Fluorescein enhancement	Represents areas of pleural/subpleural abnormality not visible with white light autofluorescence Often present at sites distinct from ELC in lungs of patients with PSP and not in those of control subjects Provides evidence of diffuse pleural porosity
Distal airway inflammation	Inflammatory infiltration with lymphocytes and macrophages within walls of bronchioles Associated fibrotic changes and compensatory emphysema

From Grundy S, Bentley A, Tschopp JM: Primary spontaneous pneumothorax: A diffuse disease of the pleura. *Respiration* 2012;83:185-189.

Figure 47.1 Large bulla at the apex of the left lung in a 12-year-old boy with recurrent primary spontaneous pneumothorax. (From Noppen M, De Keukelleire T: Pneumothorax. *Respiration* 2008;76:121-127.)

fluorescein leak (i.e., areas of potential air leak) were visualized in only a small proportion of PSP, but these areas were noted to be distinct from areas of ELC. When studied with electron microscopy, the linings of some resected areas of ELC have been shown to be almost completely absent of mesothelial cells and have abnormal pores present¹⁹ (Fig. 47.2).

Figure 47.2 Air leak identified by fluorescein-enhanced autofluorescence thoracoscopy in a 27-year-old man with recurrent primary spontaneous pneumothorax. The air leak was situated at the base of a highly vascularized, severe malformation of the apex of the lung. (From Noppen M, De Keukelleire T: Pneumothorax. *Respiration* 2008;76:121-127.)

DISTAL AIRWAY INFLAMMATION

Pathologic findings suggest an inflammatory cause to the formation of ELCs. Chronic distal airway inflammation with lymphocyte and macrophage infiltration alongside fibrotic changes and compensatory emphysema can be seen microscopically in areas of lung tissue from patients with PSP.²⁰ In a different study, the presence of respiratory bronchiolitis (RB) was seen in close to 90% of patients with PSP who underwent surgical resection in a different study.²¹ However, all these patients in this study were smokers, and smoking is a recognized cause of RB. It has been proposed that distal airway inflammation associated with PSP leads to obstructive gas trapping and consequent increases in distal airway pressure, which possibly causes air leak into the pleural space.²²

SMOKING

Cigarette smoking is a significant risk factor for PSP. It is thought to be due to the consequences of airway inflammation leading to airway obstruction with a check valve phenomenon, causing air trapping and development of pneumothorax.²² The lifetime risk is 12% in smokers compared to 0.1% in nonsmokers. Risk is also directly related to the amount of cigarette smoking. Compared to nonsmokers, the relative risk of PSP in men was seven times higher in light smokers (1-12 cigarettes per day), 21 times higher in moderate smokers (13-22 cigarettes per day), and 102 times higher in heavy smokers (>22 cigarettes per day). For women, the relative risk was 4, 14, and 68 times higher in light, moderate, and heavy smokers, respectively.²³ Cessation of smoking appears to reduce the risk of recurrence,⁹ and continued smoking increases the risk of recurrence.²⁴

RB, a form of airway inflammation associated with cigarette smoking, may contribute to the development and recurrence of PSP. In a study with 115 patients with PSP who

underwent video-assisted thoracoscopic surgery (VATS), pneumothorax recurrence rates were higher in patients with extensive rather than nonextensive RB for both nonoperative and postoperative pneumothorax.²⁵

GENETICS

Familial inheritance of pneumothorax describing the clustering of PSP in certain families has been published. Autosomal dominant, autosomal recessive, polygenic, and X-linked recessive inheritance mechanisms have been proposed.²⁶⁻²⁸ Birt-Hogg-Dubé (BHD) is an autosomal dominant cancer disorder that predisposes patients to benign skin tumors and renal cancer. It is associated with pleuropulmonary blebs and cysts that lead to PSP.²⁹ In one study of 198 patients with this syndrome, 48 patients (24%) had a history of pneumothorax.³⁰ The gene responsible for this familial cancer syndrome (*FLCN*) has been mapped to chromosome 17p11.2.^{31,32} Other mutations of *FLCN* have been associated with spontaneous pneumothorax and bullous lung disease in the absence of Birt-Hogg-Dubé syndrome.³³

Patients with Marfan syndrome are tall, and pneumothorax is a common pulmonary complication. Marfan syndrome is caused by the mutation in *FBN1* gene on chromosome 15. This gene is responsible for the formation of 10- to 12-nm microfibrils in the extracellular matrix of connective tissue. It is hypothesized that familial spontaneous pneumothorax is caused by a connective tissue disorder that exhibits mendelian inheritance and *FBN1* has been postulated as the causative gene.³⁴

CLASSIFICATION

SPONTANEOUS PNEUMOTHORAX

PRIMARY SPONTANEOUS PNEUMOTHORAX

PSP is classically seen in previously healthy young men with an asthenic body habitus. The incidence of PSP rises with increasing height among adults of both sexes, more so in men. For those 76 inches or taller, the rate was 200 per 100,000 person-years.³⁵ It is hypothesized that individuals with tall stature and low body mass index combined with smoking are predisposed to develop ELCs owing to the pressure gradient between the lung base and the apex, resulting in increased alveolar distending pressures at the apex.³⁶ Smoking, as previously described, greatly increases the risk of PSP. Smoking increases the relative risk of developing spontaneous pneumothorax about ninefold in women and 22-fold in men, and there is a statistically significant dose-response relationship between smoking and spontaneous pneumothorax.³⁷

SECONDARY SPONTANEOUS PNEUMOTHORAX

SSP has been described in a large variety of diseases including COPD with emphysema, cystic fibrosis (CF), tuberculosis, lung cancer, human immunodeficiency virus (HIV)-associated *Pneumocystis jiroveci* pneumonia, followed by more rare but “typical” disorders such as lymphangioleiomyomatosis (LAM) and histiocytosis X (Box 47.1). Because lung function in these patients is already compromised, SSP

Box 47.1 Frequent and/or Typical Causes of Primary Spontaneous Pneumothorax

Airway disease
 Emphysema
 Cystic fibrosis
 Severe asthma
 Infectious lung disease
Pneumocystis jiroveci (formerly *P. carinii*) pneumonia

often presents as a potentially life-threatening disease requiring immediate action, as opposed to PSP, which is more of a nuisance than a dangerous condition. The general incidence is almost similar to that of PSP.³⁸

Chronic Obstructive Pulmonary Disease

COPD is the most common cause of SSP, with nearly 70% of SSP attributed to COPD.³⁹ The peak incidence of SSP from COPD typically occurs later in life averaging 60 to 65 years of age.⁴⁰ The clinical presentation of pneumothorax in COPD is often atypical—pain may be absent, anxiety and breathlessness may predominate and be out of proportion to the collapsed lung, and the classic sign of hyperresonance may not be helpful because of the underlying emphysema. The air leak in these patients is usually large, and the tissues are slow to heal, so it is weeks before the tubes can be taken out.⁴¹

Pneumothorax in Drug Abusers

When the peripheral veins of chronic abusers of drugs become obliterated because of a sclerotic or infectious process, the individual may attempt to use larger veins in the groin or neck. Attempted subclavian or supraclavicular (“pocket shot”) injection of drugs in the street setting has led to unilateral or bilateral pneumothoraces.⁴²⁻⁴⁴ Douglas and Levison⁴⁵ found that the incidence of pneumothoraces is equal in both sexes and that it is less of a problem in teenagers and in addicts older than 40 years of age. It was also noted that although most drug users describe using small (21- or 22-gauge) needles, a large, complete, or tension pneumothorax usually develops.

Pneumothorax in HIV-Infected Patients

Pneumothorax is an uncommon but potentially fatal complication of HIV infection. The first report of spontaneous pneumothorax in patients with acquired immunodeficiency syndrome (AIDS) was in 1984.⁴⁶ With the diagnosis of AIDS, a patient’s risk of sustaining a nontraumatic pneumothorax increases to 450 times that of the general population.⁴⁷ It has since been described in a generalized HIV-infected population.^{48,49} Pneumothorax complicated 1.2% of all hospital admissions in a cohort of 599 HIV-infected patients followed over 3 years in a prospective observational study. There was also an associated increase in in-hospital mortality rate (31% versus 6%) for patients without pneumothorax.⁴⁸

A high incidence (2-9%) of pneumothorax has been reported in patients with AIDS and *Pneumocystis carinii* pneumonia (PCP).⁵⁰⁻⁵² *Pneumocystis carinii*, which was thought to be a protozoan, has been renamed as *Pneumocystis jiroveci* and is now classified as an archiascomycetous fungus.⁵³ Causes of pneumothorax in HIV-infected individuals include *P. jiroveci*⁵⁴⁻⁵⁷ along with other infectious agents such as *Mycobacterium tuberculosis*, *M. avium intracellulare*, pulmonary cytomegalovirus, *Pneumococcus* organisms,⁵⁴ or pulmonary toxoplasmosis.⁵⁴ Pneumothorax has also been described in HIV-infected individuals from Kaposi sarcoma.⁵⁸

The cause of pneumothorax in patients with PCP is unclear. Several investigators believe that extensive tissue invasion within the alveolar interstitium in severe PCP is an important factor in causing necrosis and subsequent pneumothorax. Several observations highlight this point. The most common sites of tissue invasion with PCP are the alveolar septa, pleurae, and vasculature.⁵⁹ Tissue invasion could cause necrosis as a result of direct tissue injury by toxins from *Pneumocystis*,⁵⁹ infarction from vascular compromise,^{60,61} or as a result of the host inflammatory response.⁶²

The administration of aerosolized pentamidine has been implicated in the pathogenesis of cavitation, cyst formation, and pneumothorax,^{50,63,64} but the biologic basis for this relationship is unknown. No direct toxic action of pentamidine on the lungs has been described, so an indirect effect may be present. Cavitation due to PCP may occur primarily in the upper lobes and periphery because aerosolized pentamidine is preferentially delivered to the proximal parenchyma of the lower lobes. Inadequate deposition of pentamidine in the periphery of the lung could allow a chronic, low-grade infection with *Pneumocystis* to persist, leading to peripheral lung destruction and pneumatocele formation. Increased survival time of AIDS patients due to prophylaxis could allow for development of these lesions.⁵⁰

Several other risk factors for AIDS-related pneumothorax have been identified. In addition to previous or active infection of *P. jiroveci* and aerosolized pentamidine, cigarette smoking and the presence of pneumatoceles on chest radiograph are risk factors.⁶⁵ The association between cigarette smoking and AIDS-related pneumothorax could be explained by subclinical obstructive disease preventing adequate deposition of aerosolized pentamidine in the lung periphery, resulting in subpleural *Pneumocystis* infection.⁶⁵ Pulmonary tuberculosis also appears to increase the risk of pneumothorax in AIDS.⁶⁶

Catamenial Pneumothorax

In most cases, catamenial pneumothorax is related to pelvic or thoracic endometriosis.^{67,68} Catamenial pneumothorax occurs typically within 24 to 72 hours after onset of menstruation. It is often recurrent and more common than previously thought. Two mechanisms have been described for pneumothorax related to endometriosis. The most common is the movement of endometrial implants to the diaphragm, preferentially to the right side because of the recognized peritoneal circulation up from the pelvis to the right side. These implants then create channels or “holes” through the diaphragm that allow the implants or air to move into the chest. The second and much less frequent cause of endometrial implants causing *pneumothorax* in the chest is through the venous implants that lodge into the lung itself.⁶⁹ Clinical manifestations of thoracic endometriosis include chest pain, dyspnea, and hemoptysis. Treatment for the prevention of recurrence is indicated after a first episode of catamenial pneumothorax because recurrences are frequent.³⁸

Cystic Fibrosis

SSP occurs in approximately 6% of all patients with CF and this number increases to 16% to 20% among those who survive to age 18.^{70,71} SSP from CF is usually due to rupture of apical subpleural cysts. The risk of pneumothorax is inversely proportional to the forced expiratory volume in 1 second (FEV₁). Other factors associated with an increased risk of pneumothorax include infection with *Pseudomonas aeruginosa*, *Burkholderia cepacia* complex, or *Aspergillus* species. A previous history of massive hemoptysis also increases risk.

NONSPONTANEOUS PNEUMOTHORAX

TRAUMATIC PNEUMOTHORAX

Pneumothorax ranks second to rib fractures as the most common sign of chest trauma. It occurs in up to 50% of chest trauma victims.⁷² Most are caused by a penetrating injury, but closed chest trauma causing alveolar rupture from thoracic compression, fracture of a bronchus, and esophageal rupture have also been reported.^{73,74} Traumatic pneumothorax can be classified as open, closed, tension, or hemopneumothorax. A tension pneumothorax should be managed immediately by decompression with a large-bore needle usually in the second anterior interspace in the midclavicular line. Open pneumothorax should have a moist sterile gauze pack placed over the open wound, followed by a chest tube. Hemopneumothorax (20% of trauma patients) requires insertion of a large-bore (28-36F) chest tube.³⁸

Occult pneumothorax may be present in half of blunt abdominal trauma patients, many of which are undetected by chest radiograph.⁷⁵⁻⁷⁹ CT of the chest should therefore always be performed in these patients. Most surgeons and emergency physicians will place a chest tube in occult and nonoccult pneumothoraces. Studies suggest, however, that clinically stable patients and those who do not have an enlarging pneumothorax may be treated conservatively, ultimately requiring chest tube placement in about 10% of cases.⁸⁰

TRAUMATIC IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothorax occurs most often following transthoracic needle biopsy (24%), subclavian vein catheterization (22%), thoracentesis (20%), transbronchial lung biopsy (10%), pleural biopsy (8%), and positive-pressure ventilation (7%).⁸¹ Diagnosis of iatrogenic pneumothorax is often delayed. Small and asymptomatic iatrogenic pneumothorax, however, often do not need any treatment and resolve spontaneously. In larger or symptomatic pneumothoraces, simple manual aspiration or placement of a small catheter or chest tube attached to a Heimlich valve is usually sufficient.⁸² Larger tubes may be necessary in patients with emphysema or when the patient is placed on a mechanical ventilator.

PULMONARY BAROTRAUMA DURING MECHANICAL VENTILATION

Pulmonary barotrauma (PBT) refers to alveolar rupture due to elevated transalveolar pressure (the alveolar pressure minus the pressure in the adjacent interstitial space). PBT was previously estimated to range between 3.8% and 41.7% of patients undergoing mechanical ventilation.⁸³ The rate in actuality may be lower because low tidal volume ventilation is becoming more common. Consequences of barotrauma include pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous emphysema.

Positive-pressure ventilation increases transalveolar pressure, which can cause alveolar rupture.⁸⁴ Alveolar rupture allows air from the alveolus to enter the pulmonary interstitium where it can dissect along the perivascular sheaths toward the mediastinum. This can lead to pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema^{85,86} (Fig. 47.3). Bronchopleural fistula,

Figure 47.3 Chest computed tomography revealing extensive subcutaneous emphysema (arrows) from the lower neck to the upper abdomen and pneumomediastinum (thick arrows). (From Lai JI, Po-Chou L, Wang WS, et al: Barotrauma related extensive pneumothorax, pneumomediastinum, and subcutaneous emphysema in a patient with acute respiratory distress syndrome with low tidal volume. *Postgrad Med J* 2010;86:567-568.)

tension pneumothorax, tension lung cyst, and subpleural air cyst have also been reported but are less common.⁸⁷

In a multicenter prospective cohort study of 5183 mechanically ventilated patients, the incidence of PBT was 3%.⁸⁸ Asthma, chronic interstitial lung disease, and acute respiratory distress syndrome (ARDS) were identified as independent risk factors for barotrauma. Other studies have also demonstrated that acute lung injury (ALI) and ARDS are independent risk factors for PBT.^{89,90} Elevated peak and plateau pressures have been identified as risk factors.^{91,92}

Neither open lung strategies using high levels of positive end-expiratory pressure (PEEP) nor recruitment maneuvers have been shown to increase the risk of barotrauma.^{93,94}

Clinical Presentation

The clinical presentation of PBT can vary. With pneumothorax, patients may complain of dyspnea or chest pain. Physical findings can include tachycardia, tachypnea, hypertension, or oxyhemoglobin saturation accompanied by unilateral reduction of breath sounds. If a tension pneumothorax develops, there may be hypotension and tracheal deviation. Patients with pneumomediastinum may complain of dyspnea and chest or neck pain. Other findings include tachycardia, tachypnea, and hypertension. A crunching sound may be heard during auscultation. Rarely, hypotension from decreased venous return and cardiac output may occur if tension pneumomediastinum develops.⁹⁵ Pneumoperitoneum may manifest itself as abdominal pain. Other physical findings include abdominal distention, tenderness, and tympany. Rarely, abdominal compartment syndrome may develop if the pneumoperitoneum progresses to a tension pneumoperitoneum.⁹⁶ Subcutaneous emphysema generally presents as painless soft tissue swelling. It typically appears in the upper chest, neck, and face. Compression of the affected areas can reveal crepitus. A rare consequence of severe subcutaneous emphysema is compartment syndrome.⁹⁷

Diagnosis

The diagnosis of pneumothorax is suspected when a patient presents with the symptoms and signs described earlier, then confirmed with a portable chest radiograph. An upright chest radiograph has the highest diagnostic yield for pneumothorax, although diagnosis in the intensive care unit (ICU) may be difficult as most patients are semirecumbent or supine.⁹⁸ In a fully upright chest radiograph, a pneumothorax appears as a radiolucent collection between the visceral and parietal pleurae in the superior portion of the chest. In contrast, when a patient is supine, free air collects in the anterior chest, displacing the costophrenic angle inferiorly, often creating a “deep sulcus” sign. The deep sulcus sign refers to a unilateral increase in the apparent size of the costophrenic angle (Fig. 47.4).

Bedside ultrasound is being used more readily in the ICU to rapidly diagnose pneumothorax. Utilizing the M-mode, the absence of “lung sliding” is indicative of the presence of a pneumothorax⁹⁹ (Video 47.1).

Tension pneumothorax is diagnosed clinically when a patient presents with unilateral absence of breath sounds, a shift of the trachea in the direction away from the absent breath sounds, and hemodynamic compromise in the appropriate setting. Immediate intervention is indicated as

Figure 47.4 Supine chest radiograph of a neonate illustrates the deep sulcus sign with abnormal deepening and lucency of the left lateral costophrenic angle (*). (From Kong A: The deep sulcus sign. *Radiology* 2003;228(2):415-416.)

there is seldom time for a radiographic evaluation. Rapid clinical improvement following empiric aspiration of a suspected tension pneumothorax is diagnostically definitive. Subsequently, a tube thoracostomy is placed for ongoing management.

Pneumomediastinum frequently coexists with pneumothorax. It is usually diagnosed with a portable chest radiograph. It typically appears as radiolucent streaks in the mediastinum (Fig. 47.5).

Pneumoperitoneum is diagnosed with a chest radiograph less than one third of the time. A suspected pneumoperitoneum is best evaluated by chest CT.¹⁰⁰ The patient should remain in position for 5 to 10 minutes before the radiograph is taken. This allows time for air to collect in a sufficient volume to be detected radiographically. Pneumoperitoneum may be identified on a supine abdominal radiograph (see Fig. 47.5). Free air accumulates anteriorly when the patient is supine and on a chest or abdominal radiograph may present in several ways. Gas appearing on both sides of the bowel wall is referred to as Rigler's sign. Gas outlining the peritoneal cavity is known as the football sign. Gas outlining the medial umbilical folds is called an inverted V sign. Gas may also outline the falciform ligament or localize in the right upper quadrant.¹⁰¹

Subcutaneous emphysema is often found by identifying crepitus during physical examination. On chest radiograph of areas of tissue swelling, it can appear as radiolucent streaks throughout the subcutaneous tissue and muscle (see Fig. 47.5).

Prevention

To prevent barotrauma, it is generally recommended that plateau airway pressure be maintained at or below 35 cm H₂O. Plateau pressure is the most indicative of the alveolar

Figure 47.5 Chest radiographs revealing the presence of subcutaneous emphysema, pneumomediastinum, and pneumoperitoneum (arrows). (From Alexiou K, Sakellariadis T, Sikalias N, et al: Subcutaneous emphysema, pneumomediastinum and pneumoperitoneum after unsuccessful ERCP: A case report. *Cases J* 2009;2:120.)

pressure and therefore is the measure of greatest concern for the prevention of PBT. Lower plateau airway pressures have been associated with a lower incidence of PBT. A threshold pressure appears to exist at 35 cm H₂O, above which there is a higher incidence of barotrauma. A meta-analysis of 14 clinical trials demonstrated a strong relationship between PBT and a plateau airway pressure greater than 35 cm H₂O or a static compliance less than 30 mL per cm H₂O.¹⁰² There have not been direct comparisons between management targeting a plateau airway pressure or peak airway pressure. Peak airway pressure is likely a less reliable predictor of PBT given the conflicting data.¹⁰³⁻¹⁰⁹

Management

The best treatment for PBT is early recognition, and immediate attempts should be made to reduce plateau airway pressure.⁸³ This may require lowering the tidal volume or PEEP, as well as increasing sedation, administering neuromuscular blockade, or advancing treatment of the underlying condition. In cases of pneumothorax while on a mechanical ventilator, there is no high-quality evidence that supports routine insertion of chest tubes for all patients. However, more than 30% of pneumothoraces in mechanically ventilated patients progress to tension pneumothoraces, indicating that these patients must be monitored closely. Treatment for mechanically ventilated patients who develop a pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema is generally supportive unless there is evidence of tension pneumomediastinum or compartment syndrome from pneumoperitoneum or subcutaneous emphysema.⁹⁵

Prognosis

PBT appears to be associated with increased mortality rate, even though barotrauma is not a direct cause of death in most patients. In a multicenter prospective cohort study, patients with barotrauma had a significantly higher mortality rate (51% versus 39%), a longer length of ICU stay (median 9 versus 7 days), and a longer duration of

mechanical ventilation (median 6 versus 4 days) than patients without barotrauma.⁸⁸ Mortality rate may be related to the severity of the PBT. In one retrospective cohort study of 1700 mechanically ventilated patients, the mortality rate approached 100% when PBT caused a large (>500 mL per breath) bronchopleural fistula.¹⁰⁹ High-frequency jet ventilation is FDA (Food and Drug Administration) approved for the management of large bronchopleural fistulas, but this may be outweighed in some patients by increased plateau airway pressure (alveolar pressure), decreased oxygenation, or worse hypercapnia.¹¹⁰

PNEUMOTHORAX AFTER FIBEROPTIC BRONCHOSCOPY AND NEEDLE BIOPSY OF THE LUNG

Multiple literature reviews have documented the relative safety of fiberoptic bronchoscopy (FOB) with transbronchial biopsy. One review of more than 9000 such procedures found that the rate of pneumothorax was 1.9%.¹¹¹ An immediate postbronchoscopic chest radiograph rarely provides clinically useful information, and in FOB without transbronchial biopsy an immediate postbronchoscopy radiograph is not necessary.^{112,113} Another study in 2006 concluded that in asymptomatic patients, routine radiograph after transbronchial biopsy is not necessary.¹¹⁴ It was determined that certain patient populations should have routine radiographs performed after FOB with transbronchial biopsy: comatose or mentally retarded patients, patients receiving positive-pressure ventilation, patients with severe respiratory compromise as a result of disease or surgery, patients with bullous disease, patients who complain of chest pain, and outpatients. Pneumothorax after bronchoalveolar lavage without biopsy is extremely rare. The complication of pneumothorax after transbronchial needle aspiration is also low.¹¹⁵

Pneumothorax is the most common complication of needle aspiration or biopsy of the lung. It has been reported to occur in 17% to 26.6% of patients.¹¹⁶⁻¹¹⁹ The chest tube insertion rate is much lower, ranging from 1% to

14.2%.¹¹⁶⁻¹¹⁹ Risk factors for the development of biopsy-related pneumothorax include the presence of COPD, the absence of a history of ipsilateral surgery, small lesion size, a long needle path, and repeated pleural puncture.¹¹⁶⁻¹²¹ Enlarging or symptomatic pneumothorax can be managed by manual aspiration or placement of a small-caliber chest tube.¹²⁰

Delayed pneumothorax after percutaneous fine-needle aspiration has been reported. A study by Choi and colleagues¹²² reported on their series of 458 patients who had undergone transthoracic needle biopsy. A follow-up chest radiograph was obtained immediately and at 3, 8, and 24 hours after the biopsy procedure. A pneumothorax that developed after 3 hours was defined as delayed pneumothorax. Pneumothorax developed in 100 of the 458 patients (21.8%), and delayed pneumothorax developed in 15 patients (3.3%). Female gender and absence of emphysematous changes correlated with an increased rate of delayed pneumothorax.

PNEUMOTHORAX AFTER THORACENTESIS

According to a 1998 National Center for Health Statistics study,¹²³ physicians perform an estimated 173,000 thoracenteses annually in the United States. Iatrogenic pneumothoraces resulting from thoracentesis increase morbidity rate, mortality rate, and length of hospitalization. Previous reports indicated chest tube insertion may be required in up to 50% of cases with a mean duration of placement of approximately 4 days.^{124,125} Gordon and colleagues¹²⁶ performed a systematic review and meta-analysis of 24 studies reporting pneumothorax rates after thoracentesis involving 6605 thoracenteses. The overall pneumothorax rate was 6%. In cases in which pneumothorax developed, 34.1% required chest tube placement. Statistically significant risk factors for developing thoracentesis included performing thoracentesis as a therapeutic procedure as opposed to as a diagnostic procedure; the presence of cough, dyspnea, or chest pain during the procedure; and witnessing the aspiration of air during the procedure.¹²⁶ Although not statistically significant, other possible predictors included the need for two or more needle insertions and concurrent mechanical ventilation.¹²⁶ Ultrasonography guidance,¹²⁷⁻¹²⁹ more experienced operators,¹³⁰ and fewer needle passes conferred lower complication rates,¹³¹ which paralleled findings from central venous catheter insertion studies. Various mechanisms may explain the pneumothoraces that occur after thoracentesis: the lung may be punctured at the time of needle entry or after the fluid has been withdrawn, or a small amount of air may be drawn into the chest during aspiration or along the needle track if high negative intrapleural pressure develops.¹³²

PNEUMOTHORAX RESULTING FROM NASOGASTRIC FEEDING TUBES

Small-bore Silastic feeding tubes are being used with increasing frequency for short- and long-term enteral hyperalimentation. The first reported case of pneumothorax as a complication of passing a narrow-bore feeding tube was in 1978.¹³³ This once rare complication has now become more common.¹³⁴⁻¹³⁶ Narrow-bore feeding tubes are particularly likely to give rise to pneumothorax because of the tube's small diameter (2.7 mm), self-lubricating properties, and

wire stylet. These factors allow undetected entry of the tube into the tracheobronchial tree, perforation of pulmonary tissue, and lodging in the pleural cavity.¹³⁷ Other factors that increase the risk of a misplaced feeding tube include the presence of an endotracheal or tracheostomy tube (these may increase pulmonary passage of the tube by preventing glottis closure and perhaps by inhibiting swallowing), altered mental status, denervation of airways, esophageal stricture, enlargement of the heart, and neuromuscular weakness.¹³⁸ The clinical signs commonly used to determine correct placement of the feeding tube may be misleading. Normally, to confirm the correct placement of a feeding tube in the stomach, a small amount of air is injected. This produces a characteristic gurgle in the left upper quadrant of the abdomen, but a "pseudoconfirmatory gurgle" with a feeding tube in the chest has been reported.¹³⁹ Aspiration of large amounts of fluid through the tube is also taken to be a test of correct placement into the stomach, but delayed aspiration of a large quantity of undigested feeding solution from the pleural space, mistaken for gastric contents, has been reported.¹⁴⁰

PNEUMOTHORAX AFTER PERCUTANEOUS DILATIONAL TRACHEOSTOMY

Percutaneous dilational tracheostomy (PDT) was first described in 1985 by Ciaglia and colleagues.¹⁴¹ A case series described subcutaneous emphysema and pneumothorax as complications after percutaneous tracheostomy in a series of 326 cases.¹⁴² Their review of the literature showed that the incidence of subcutaneous emphysema was 1.4% and that of pneumothorax was 0.8%. Findings associated with pneumothorax included difficult PDT and the use of a fenestrated cannula.

SPECIAL SITUATIONS

PNEUMOTHORAX EX VACUO

Pneumothorax after partial resolution of total bronchial obstruction,¹⁴³ as a complication of lobar collapse,¹⁴⁴ and after therapeutic thoracentesis for malignant effusions¹⁴⁵ has been described. Acute lobar collapse results in a sudden increase in negative pleural pressure surrounding the collapsed lobe. Although the parietal and visceral pleural surfaces remain intact, the gas originating from the ambient tissues and blood is drawn into the pleural space, producing a pneumothorax called *pneumothorax ex vacuo*. Recognition of this type of pneumothorax is crucial because managing it requires relieving the bronchial obstruction rather than inserting a chest tube. The diagnosis of trapped lung requires documentation of chronicity and absence of pleural inflammation, pleural malignancy, or endobronchial lesion. The pathognomonic radiographic sign of a trapped lung is the pneumothorax ex vacuo, characterized as a small to moderate-sized air collection after evacuation of effusion.¹⁴⁶

SPORT-RELATED PNEUMOTHORAX

Pneumothorax as a result of blunt trauma from contact sports is a recognized but underreported event. Several cases of pneumothorax or pneumomediastinum sustained during a contact sport have been described in the literature.^{147,148} In a large case series, Kizer and MacQuarrie¹⁴⁹

identified 20 patients who had sustained a spontaneous or traumatic air leak while engaged in an outdoor sport.

BAROTRAUMA UNRELATED TO MECHANICAL VENTILATION

Although the term *barotrauma* has traditionally been used to describe the development of extra-alveolar air while on mechanical ventilation, in other instances it may be due to increased intra-alveolar pressure, causing air to leak out of the alveoli. PBT of ascent is a well-known complication of compressed air diving. Pulmonary edema and hemorrhage occur when lung volume decreases below residual volume. As a diver ascends and transalveolar pressure exceeds 20 to 80 mm Hg, overexpansion injury in the form of alveolar rupture can occur.¹⁵⁰⁻¹⁵² Divers who hold their breath as they ascend and those with obstructive airway diseases, such as asthma or COPD, are at increased risk.¹⁵³

Pneumothorax is a relatively uncommon complication in divers, developing in only approximately 10% of those with evidence of barotrauma. Patients with a history of spontaneous pneumothorax, bullae, or cystic lung disease are at increased risk of pneumothorax and should be cautioned against diving.¹⁵⁴

Pneumothorax develops when gas ruptures from the lung parenchyma into the pleural space. If this occurs at a significant depth, the pleural gas expands as the diver ascends (as described by Boyle's law) and can result in a tension pneumothorax. Manifestations include dyspnea, chest pain, tachycardia, hypotension, cyanosis, distended neck veins, tracheal deviation, hyperresonance to percussion, unilateral decrease in breath sounds, and accompanying subcutaneous emphysema in approximately 25% of cases.

If a pneumothorax results in severe hypoxemia or hemodynamic compromise, immediate pleural decompression is required. This is usually accomplished by inserting a large-bore needle into the second intercostal space in the midclavicular line of the affected hemithorax, followed by tube thoracostomy.

TENSION PNEUMOTHORAX

With a tension pneumothorax, the pleural pressure in the affected hemithorax exceeds atmospheric pressure, specifically during expiration. This is usually the result of a "check valve" mechanism that facilitates the ingress of gas into the pleural space during inspiration but blocks the escape of gas from the pleural space during expiration. The results are the accumulation of gas leading to a buildup of pressure within the pleural space. There is eventual respiratory failure from compression of the contralateral normal lung followed by circulatory collapse with hypotension and subsequent traumatic arrest with pulseless electrical activity (PEA) due to obstruction of venous return to the heart.

The classic signs of a tension pneumothorax are deviation of the trachea away from the side with the tension, an increased percussion note, and a hyperexpanded chest that moves little with respiration. Radiographically, tension pneumothorax shows a distinct shift of the mediastinum to the contralateral side and flattening or inversion of the ipsilateral hemidiaphragm (Fig. 47.6). Clinically unstable patients should undergo immediate needle decompression

Figure 47.6 Chest radiograph of a left tension pneumothorax in a trauma patient. Note the mediastinal shift to the right, widened rib spacing, and posterior rib fractures on the left. A flattening of the left hemidiaphragm is also present (not shown). (From Barton E: Tension pneumothorax. *Curr Opin Pulm Med* 1999;5(4):269.)

followed by chest tube insertion. Decompression is performed by advancing a standard 14- or 16-gauge intravenous catheter into the pleural space at the junction of the midclavicular line and the second or third intercostal space. The needle is advanced until air can be aspirated into a syringe connected to the needle. The needle is withdrawn and the cannula is left open to air. An immediate rush of air out of the chest indicates the presence of a tension pneumothorax. The maneuver essentially converts a tension pneumothorax into a simple pneumothorax. A chest tube can then be placed.

CLINICAL FEATURES

PSP usually occurs when the patient is at rest.¹⁵⁵ Patients are typically in their early 20s when presenting with PSP, which is rare after age 40. Chest pain and dyspnea are the two main symptoms associated with the development of pneumothorax. One series evaluated 39 patients who presented with one of the two symptoms and 64% of them had both.¹⁵⁶ The pain is generally reported as ipsilateral, which usually resolves spontaneously within 24 hours.⁴⁰ The degree of dyspnea depends on the size of the pneumothorax and the condition of the underlying lung. Cough, malaise, orthopnea, and hemoptysis may also be presenting symptoms.

Physical examination can be normal in small pneumothoraces. Possible physical findings when a large pneumothorax is present include decreased chest excursion on the affected side, diminished breath sounds, and hyperresonant percussion. There may also be subcutaneous emphysema.

Labored breathing accompanied by hemodynamic compromise (tachycardia or hypotension) suggests a possible tension pneumothorax, which necessitates emergency decompression. Tension pneumothorax occurs due to the presence of a ball-valve mechanism; air enters the pleural cavity but cannot escape. As a result, positive pressure builds up. As the tension continues to increase, the diaphragm is flattened, the mediastinum is shifted to the opposite side, and ultimately cardiopulmonary collapse results.

Hypoxemia is common because collapsed and poorly ventilated portions of lung continue to receive significant perfusion. However, hypercapnia is unusual because underlying lung function is relatively normal and adequate alveolar ventilation can be maintained by the contralateral lung.¹⁵⁷ Acute respiratory alkalosis may be present if pain, anxiety, or hypoxia is substantial.

In certain situations, the symptoms of pneumothorax may have an atypical presentation and therefore require a high index of suspicion. During a transbronchial biopsy, a patient may complain of pleuritic chest pain followed by dyspnea. A pneumothorax after a subclavian vein catheterization may present with progressive dyspnea and an alteration of vital signs. In a mechanically ventilated patient, the initial presentation may include hypotension, new-onset respiratory distress, unilateral decrease in breath sounds, a decrease in static and dynamic compliance, and worsening oxygenation.^{41,158,159}

Simultaneous bilateral pneumothoraces is a rare condition because, in humans, the left and right pleural spaces are completely separated. Patients can develop a persistent pleuro-pleuro channel after undergoing a median sternotomy, mediastinal surgery, or heart or heart-lung transplant surgery. This condition has been dubbed “iatrogenic buffalo chest” because the North American buffalo is one of few mammals that have communicating pleural spaces.¹⁶⁰ A unilateral thoracic procedure in this situation has been described to cause bilateral pneumothoraces^{161,162} and “shifting pneumothorax.”¹⁶³ Simultaneous bilateral spontaneous pneumothorax (SBSP) has been described in a case series with 12 patients.¹⁶⁴ Of the 12 patients, 5 had no underlying lung disease. In 7 patients, SBSP was secondary to pulmonary metastases, histiocytosis, undefined interstitial pulmonary disease, tuberculosis, pneumonia, and COPD.

ELECTROCARDIOGRAPHIC FEATURES

The presence of a pneumothorax may lead to distinct electrocardiographic changes, which can be mistaken for myocardial ischemia or infarction. Most findings have been described for left-sided pneumothorax. Poor R wave progression in the anterior precordial leads with a decrease in R wave from V₄ to V₅, rightward shift of frontal axis, diminution of precordial R voltage, decrease in QRS amplitude, and precordial T-wave inversion have all been described.¹⁶⁵⁻¹⁶⁷

The absence of ST-segment elevation and a significant Q wave and reversal of electrocardiographic changes in the sitting position suggest pneumothorax. In right-sided pneumothorax, there is a loss of S wave in lead V₂ and prominent R-wave voltage, which may mimic posterior wall myocardial infarction.¹⁶⁸

DIAGNOSTIC IMAGING MODALITIES

RADIOGRAPHIC SIGNS

Chest radiography and CT are the first-line imaging modalities used to identify a pneumothorax. The main feature of a pneumothorax on a chest radiograph is a white visceral pleural line. This line separates the visceral pleura from the parietal pleura by a collection of gas (Fig. 47.7). A pneumothorax may be identified using an upright, supine, or lateral decubitus chest radiograph. The lateral decubitus view is the most sensitive, and the supine view is the least sensitive.

UPRIGHT CHEST RADIOGRAPH

In an upright patient with a pneumothorax, most pleural gas accumulates in an apicolateral location. The visceral pleural line appears either straight or convex toward the chest wall. As little as 50 mL of pleural gas may be seen on a chest radiograph.¹⁶⁹ Although there is generally a loss of lung volume with a pneumothorax, the collapsed lung preserves its translucency because hypoxic vasoconstriction diminishes the blood flow to the collapsed lung. The value of obtaining an expiratory chest radiograph has been overstated. Inspiratory and expiratory upright chest radiographs detected pneumothorax with equal sensitivity.¹⁷⁰

SUPINE CHEST RADIOGRAPH

In a supine patient with a pneumothorax, most pleural gas accumulates in a subpulmonary location. A “deep sulcus” sign occurs when gas outlines the anterior pleural reflection, the costophrenic sulcus, and the anterolateral border

Figure 47.7 Radiograph of right lung pneumothorax. Arrow points to collapsed lung.

of the mediastinum (see Fig. 47.4). Rarely, pleural gas can accumulate in the phrenicovertebral sulcus. The visceral pleural line may be seen at the lung base and has a concave contour. Around 500 mL of pleural gas is needed in order to definitively diagnose pneumothorax on a supine chest radiograph.¹⁶⁹

LATERAL DECUBITUS CHEST RADIOGRAPH

A pneumothorax is most easily detected with a lateral decubitus view. Most pleural gas in this position accumulates in the nondependent lateral location. The visceral pleural line appears as a straight or convex line toward the chest wall. As little as 5 mL of pleural gas may be visible on a lateral decubitus view.¹⁶⁹

COMPUTED TOMOGRAPHY

CT scanning is the most accurate imaging modality for the detection of pneumothorax although it is generally not the initial option. This method can identify small amounts of intrapleural gas, atypical collections of pleural gas, and loculated pneumothoraces. Complex pleural disease such as pleural effusion and cystic lung disease is optimally displayed by CT scanning.¹⁷¹

PULMONARY ULTRASONOGRAPHY

Ultrasound was first used to detect pneumothorax in a horse in 1986 and then in humans shortly thereafter.¹⁷² In a normal lung, the visceral and parietal pleurae are adjacent, and ultrasound shows shimmering or sliding at the pleural interface during respiration.¹⁷³ The absence of “lung sliding” indicates a pneumothorax. Comet tails are an ultrasound artifact that arises when ultrasound encounters a small air-fluid interface (Fig. 47.8). The presence of “sliding lung” and “comet tail” artifacts appear to reliably rule out pneumothorax (Video 47.1). The presence of a “lung point” sign is nearly 100% specific for the detection of pneumothorax. Here the visceral pleura is seen to be intermittently coming into contact with the chest wall during inspiration. The lung point sign may also be helpful in determining the actual size of the pneumothorax (Fig. 47.9). A review of four prospective studies found the sensitivity and specificity of ultrasound for pneumothorax to range from 86% to 98%, which was superior to supine chest radiography (sensitivity 28-75%).¹⁷⁴ A small pneumothorax may be missed with ultrasound, and patients with blebs or scarring may have a false-positive finding.¹⁷⁵

DIFFERENTIAL DIAGNOSIS: CONDITIONS MIMICKING PNEUMOTHORAX

Large subpleural bullae can mimic a loculated pneumothorax. Bullae can be distinguished from pneumothorax due to the fact that only bullae typically have a medial border that is concave to the chest wall.¹⁷⁶ Exceptions to this distinction occur with subpulmonary collections of gas, loculated collections of gas, and pleural adhesions. In trauma cases, the stomach can herniate into the chest following rupture of the left hemidiaphragm, and a gas-filled stomach may be mistaken for a loculated pneumothorax.

Figure 47.8 Rib shadows (R) are visible as bright reflectors with distal shadow. The pleura (* *) is a bright echogenic line beneath the ribs. Comet tail artifacts (arrows) arise from normal pleura reflecting sound waves. (From Mt. Sinai Emergency Ultrasound Division Tutorials. Accessed at <http://sinaiem.us/tutorials/pneumothorax>.)

Figure 47.9 Lung point sign. B-mode depicting the lung point: Sliding lung touching the chest wall. (From Husain LF, Hagopian L, Waymen D, et al: Sonographic diagnosis of pneumothorax. J Emerg Trauma Shock 2012;5:76-81.)

This can be disastrous if drainage with a thoracostomy tube is attempted. A skinfold can generally be distinguished from a pneumothorax by careful evaluation of the radiograph. Skinfolds generally extend beyond the rib cage, stop short of the ribs, and gradually increase in opacity with an abrupt dropoff at the edge of the image. Blood vessels often extend beyond the skinfold.¹⁷⁷

MANAGEMENT

Figure 47.10 represents an algorithmic approach to the management of pneumothorax.

MANAGEMENT OF THE FIRST EPISODE OF PNEUMOTHORAX

Initial management is directed at removing air from the pleural space followed by preventing recurrence. Approaches for the management of the initial episode include observation, supplemental oxygen, simple aspiration of the pneumothorax, and tube thoracostomy. The choice of therapy in a given patient depends on various factors such as size of the pneumothorax, whether the pneumothorax is primary or secondary, the condition of the lungs, the clinical stability of the patient, the outcome of the patient, and whether the pneumothorax has occurred in a special setting. Various guidelines for managing pneumothorax have been published.^{178,179}

ESTIMATING THE SIZE OF A PNEUMOTHORAX

Determining the size of a pneumothorax is difficult. The average interpleural distance (AID) approximates the size of a pneumothorax from a frontal chest radiograph by taking the sum of the distances in millimeters between the ribs and the visceral pleura at the apical, midthoracic, and basal levels and then dividing the sum by three. Another

method is called the Light Index. It uses the following calculation to estimate the size of a pneumothorax:

$$\% \text{ pneumothorax} = 100 - (D_L^3 / D_H^3 \times 100)$$

D_L is diameter of the collapsed lung **cubed**.

D_H is diameter of hemithorax on collapsed side **cubed**.

Both methods express the size of the pneumothorax as a percentage, although the Light method better correlates with the amount of pneumothorax gas removed by suction.^{180,181}

These methods are difficult to apply and tend to underestimate the size of a pneumothorax. As a result, some clinicians tend to describe a pneumothorax as large or small rather than utilize percentages. The American College of Chest Physician guidelines defines a small pneumothorax as less than 3 cm in apex-to-cupola distance.¹⁷⁸ British Thoracic Society guidelines define a pneumothorax as small if the distance from chest wall to visceral pleural line is less than 2 cm. They define a large pneumothorax if the distance from the chest wall to the visceral pleural line is 2 cm or greater.¹⁷⁹

TREATMENT OPTIONS

SUPPLEMENTAL OXYGEN

The choice of treatment depends on patient characteristics and clinical circumstances. Patients who are clinically stable and are having their first PSP can be observed with administration of supplemental oxygen if their pneumothorax is small (≤ 2 to 3 cm between the lung and chest wall on a chest radiograph).¹⁸² Supplemental oxygen is used to facilitate reabsorption of pleural air, and its importance should not be underestimated. The absorption of gas depends in part on the gradient between the partial pressure in the capillaries and that in the pleural space. On room air, the net gradient is only 54 mm Hg, whereas it exceeds 550 mm Hg when the patient is on 100% oxygen.¹⁸⁰ A normal rate of reabsorption is 1.25% of the volume of the hemithorax per 24 hours.⁷ The rate of reabsorption increases sixfold if humidified 100% oxygen is administered.¹⁸³ Therefore, hospitalized patients with any type of pneumothorax who are not subjected to aspiration of air or tube thoracostomy should be treated with supplemental oxygen at high concentrations.¹⁸⁴

REMOVAL OF AIR FROM PLEURAL SPACE

In a patient whose pneumothorax is large (more than 20-25%), progressive, tension type, or symptomatic or who has an underlying chronic lung disease, is on a ventilator, or has a recurrent pneumothorax, the pleural space air should be removed. Several therapies have been developed for this purpose.

ASPIRATION

Simple aspiration is most easily accomplished by using a commercially available thoracentesis kit. An 18-gauge needle with an 8 to 9F catheter is inserted in the second intercostal space in the midclavicular line. Once the catheter is inserted into the pleural space, the catheter is threaded deeper into the pleural space, and then the needle is withdrawn. Air is manually withdrawn through the indwelling catheter until

Figure 47.10 Reexpansion pulmonary edema. (From Tung YW, Lin F, Yang MS, et al: Bilateral developing reexpansion pulmonary edema treated with extracorporeal membrane oxygenation. *Ann Thorac Surg* 2010;89:1268-1271.)

no more can be aspirated. If the lung has not expanded after 4 L have been aspirated, then it is assumed there is a persistent air leak. Thoracoscopy should then be performed. A chest tube should be inserted if thoracoscopy is not readily available.

Once no further air can be aspirated, one of two methods may be approached.¹⁸⁵ A closed stopcock can be attached and the indwelling catheter secured to the chest wall. After 4 hours, a chest radiograph should be obtained and if there is adequate lung expansion, the catheter can be removed. Following another 2 hours of observation, another chest radiograph should be performed. If the lung remains expanded on this chest radiograph, the patient can be discharged.¹⁸⁶ Alternatively, the catheter can be left in place and attached to a Heimlich (i.e., one-way) valve. The patient can then be discharged with follow-up within 2 days.^{178,187} One advantage of aspiration over tube thoracostomy is that the patient need not be hospitalized whether the catheter is removed after aspiration or left attached to the Heimlich valve. There is a lower morbidity rate compared to tube thoracostomy and the procedure is better tolerated. Outcomes have been found to be similar between thoracostomy and aspiration. In a meta-analysis of three randomized, controlled trials (194 patients) that compared aspiration versus tube thoracostomy, aspiration resulted in shorter hospitalization stays and similar clinical outcomes.¹⁸⁸ In another randomized trial, 137 patients who had a first episode of PSP were assigned to receive manual aspiration versus tube thoracostomy. The groups had similar rates of immediate (62 versus 68%) and 1-week success (89 versus 88%). Aspiration was associated with a shorter hospital stay (1.8 versus 4 days).¹⁸⁹

TUBE THORACOSTOMY

If necessary, most patients with PSP can be managed with a small chest tube (≤ 22 F) or chest catheter (≤ 14 F).^{190,191} In the absence of trauma and with good aseptic technique, prophylactic antibiotics are not recommended.¹⁹² The preferred location for insertion of the chest tube is via an incision at the fourth or fifth intercostal space in the anterior or midaxillary line.¹⁹³⁻¹⁹⁵ In men, this corresponds to the nipple line and in women, to the inframammary crease. It is important to direct the tube anteriorly because the tube tends to track between the lobes in patients who have complete fissures. If this happens, the tube may get walled off by the lung and cease functioning. The second intercostal space in the midclavicular line has been suggested as an alternative site for tubes, but this requires placement through the pectoralis muscle. This chest tube site is more painful for the patient and the tube is more difficult to dress and manage. Once an insertion site is identified, the tube is inserted using blunt dissection and secured in place.

The chest tube can then be connected to a water seal device, with or without suction and left in position until the pneumothorax resolves. Once the air leak has resolved, the lung has fully expanded, and the pleural air removed, then the chest tube can be removed in a sequential fashion. The chest tube can generally be removed if there is no visible air leak present and air does not accumulate when suction is removed. If there is any question as to whether an air leak has resolved, a "clamp trial" can be performed. This involves clamping the chest tube and performing a chest radiograph

repeated at intervals (e.g., 2, 6, and then 12 hours). If air does not reaccumulate, the tube can be removed.

PERCUTANEOUS PNEUMOTHORAX CATHETERS AND THORACIC VENTS

Alternatives to tube thoracotomy involve using small-lumen catheters or thoracic vents (one-way valve feature). Small catheter tubes have the advantages of ease of insertion, good response, and low incidence of complications. Liu and colleagues reported that in their study using pigtail catheters in 50 patients versus traditional chest tubes in 52 patients that the pigtail drainage was no less effective than the traditional chest tube.¹⁹⁶ Complications can include catheter failure from kinking, malposition, inadvertent removal by the patient, and occlusion of the tube or valve by pleural fluid. A thoracic vent can also be used to manage a simple pneumothorax.^{197,198} It is inserted in the second intercostal space in the midclavicular line. This device has the advantages of a urethane tube that does not kink, a self-contained one-way valve, and a unique signal diaphragm that reflects pleural pressure. This device is not suitable for use in patients who are expected to have large-volume or protracted air leaks.

THORACOSCOPY

VATS is an effective treatment of PSP.¹⁹⁹⁻²⁰¹ Pleurodesis is created by pleural abrasion or a partial parietal pleurectomy. When necessary, an endoscopic stapler can be used to resect bullae.²⁰²⁻²⁰⁵

PERSISTENT AIR LEAK AND BRONCHOPLEURAL FISTULA

If a lung is at least 90% inflated but an air leak is present after 3 days, more aggressive treatment may be warranted. The simplest approach is to attach the chest tube to a unidirectional flutter valve such as a Heimlich valve. This allows rapid discharge of the patient with subsequent outpatient follow-up. An alternative approach is to perform an autologous blood patch.^{206,207} This involves withdrawing blood from the patient's peripheral vein and aseptically infusing the blood into the pleural space through the chest tube. The ideal amount of blood to infuse is not known. The range in different series has been 24 to 200 mL. After infusion of the blood, the tubing from the chest tube is draped over a hook approximately 60 cm above the patient's head and then down to a water seal device on the floor. The chest tube is then removed 24 hours after cessation of the air leak. The most serious side effect is empyema, which occurred in 9% of patients in one series.²⁰⁸ Lastly, if the lung is less than 90% expanded and the patient has a persistent air leak, the preferred intervention is VATS. An air leak persisting for more than 7 days is termed a *bronchopleural fistula* and can occur in up to a third of pneumothorax cases.²⁰⁹ After 7 days of a persistent air leak, tube thoracostomy is deemed to have failed and more definitive treatment such as surgery or pleurodesis can be planned.

RECURRENCE PREVENTION

Once the initial episode of pneumothorax has resolved, the decision to prevent future pneumothoraces must be

made. Different recurrence rates have been reported in the literature; from 20% to 52% after the first PSP.²¹⁰⁻²¹² In the following groups of patients, further management against recurrence is recommended: recurrent pneumothorax, patients with chronic air leak, patients with large bullae, patients who live in remote areas, and patients in which a recurrence could be a hazard (e.g., airline personnel or divers). The following are established risk factors for recurrence: more than one previous episode, COPD, air leak for more than 48 hours after first episode, and large cysts seen on radiograph. The following are possible risk factors for recurrence: nonoperative management of first episode (versus tube drainage) and tube drainage for only 24 hours during first episode (versus 3 to 4 days). Further management in these high-risk groups is aimed at preventing recurrence. Therapies to prevent recurrence include chemical pleurodesis, VATS, or surgical thoracotomy.

CHEMICAL PLEURODESIS

In patients who are unable or unwilling to undergo VATS, pleurodesis (adhesion of visceral and parietal pleura) can be done by introducing the sclerotic agent via the chest tube. Tetracycline had been used for pleurodesis,²¹³ but sterile tetracycline is no longer available. As a result, intrapleural instillation of doxycycline has been used as an alternative for pleurodesis.²¹⁴ Intrapleural doxycycline can be painful, so it is recommended that patients be premedicated with analgesics or anxiolytics. Talc slurry, which is composed of finely powdered magnesium silicate, can also be used for pleurodesis.²¹⁵⁻²¹⁷ Recurrence rates after treatment vary between 5% and 8%. Controversy exists whether talc should be used as a sclerosant in young, otherwise healthy individuals due to safety concerns and fear of long-term complications. Intrapleural injection of talc for malignant pleural effusions has been associated with development of ARDS in 1% to 2% of patients.²¹⁸ Extensive pleural thickening and calcifications were reported in another patient years after treatment.²¹⁹ However, several studies support the safety of talc pleurodesis for prevention of recurrent pneumothorax.^{215,220,221}

VIDEO-ASSISTED THORACOSCOPIC SURGERY PLEURODESIS

VATS is effective not only in the treatment of spontaneous pneumothorax but also in the prevention of recurrent pneumothorax.^{222,223} The rate of recurrence is less than 5% after VATS with bleb/bullae resection and pleurodesis. Mechanical pleurodesis with dry gauze, chemical pleurodesis with talc, and laser ablation of the parietal pleura are among the techniques used.

SURGICAL THORACOTOMY

Surgical management for the first episode of spontaneous pneumothorax is indicated under the following circumstances: 3% to 4% of patients have a persistent leak resulting from a large fistula that needs to be closed surgically; about 5% of patients have frank hemothorax and surgical intervention is required to control the bleeding; and a trapped lung that fails to reexpand may require decortication.

The indications for open thoracotomy are the same as those for VATS. Thoracoscopy has virtually replaced open

thoracotomy in the management of spontaneous pneumothorax due to shorter hospitalizations and less postoperative pain.^{224,225} Thoracotomy is recommended only if thoracoscopy is unavailable or has failed.

MANAGEMENT UNDER SPECIAL CIRCUMSTANCES

SECONDARY SPONTANEOUS PNEUMOTHORAX

Patients with SSP should be hospitalized owing to their diminished pulmonary reserve from their underlying lung disease. Patients with a small pneumothorax (≤ 2 cm between the lung and chest wall on a chest radiograph) who are clinically stable may be observed. Patients with a large pneumothorax or who are clinically unstable should have a chest tube placed. Tube thoracotomy is generally preferred over needle aspiration because it is more likely to be successful. In one trial, tube thoracostomy was more likely to have the pleural air completely evacuated than with needle aspiration (93% versus 67%).²²⁶ About 80% of patients with SSP will have lung expansion and cessation of their air leak within 7 days after tube thoracostomy.^{227,228} Patients who are on mechanical ventilation or who are at risk for a large air leak should be managed with a 24 to 28F chest tube. A smaller chest tube (16 to 22F) is preferred for most other patients. The chest tube should be connected to a water seal device with or without suction. In general, the chest tube should remain in place until a procedure is performed to prevent a recurrent pneumothorax. Patients who decline preventive interventions can have their chest tube clamped 12 hours after the last evidence of an air leak. A chest radiograph should be done 24 hours after the last evidence of an air leak, and if the pneumothorax has not recurred, the chest tube can be removed.

PNEUMOTHORAX IN HIV-INFECTED PATIENTS

Because the majority of pneumothoraces in HIV-infected patients occurs in association with *P. jiroveci*, all HIV-infected patients who present with a pneumothorax should undergo a diagnostic evaluation for *P. jiroveci* infection. *P. jiroveci* pneumonia-related pneumothorax is complicated by a virulent form of necrotizing subpleural lesions, which result in diffuse air leaks that are refractory to standard treatment.²²⁹ Asymptomatic patients with a small pneumothorax (less than 15-20%) may be observed. Symptomatic patients and those with a larger pneumothorax will need chest tube thoracostomy and those with a persistent air leak will likely need additional therapy with video-assisted thoracoscopy for stapling and pleurodesis. Patients who are poor operative candidates may benefit from bedside pleurodesis.

PNEUMOTHORAX IN CYSTIC FIBROSIS

Pleurodesis as an initial step in the management of pneumothorax in CF is considered contraindicated because it results in extensive pleural adhesions that jeopardize subsequent lung transplantation.²³⁰ If initial tube thoracostomy does not bring resolution of air leak within 5 days, blebectomy should be performed. If blebectomy is unsuccessful, a definitive pleural ablative procedure should be considered.

CATAMENIAL PNEUMOTHORAX AND PNEUMOTHORAX COMPLICATING PREGNANCY

The initial episode is managed in the usual manner. Recurrences, which occur 72 hours before or after menstrual flow, are managed by pleurodesis or hormonal treatment.²³¹ Therapeutic options include oral contraceptive pills, danazol, progestational agents, and gonadotropin-releasing hormone (GnRH) analogs.⁶⁹ Thoracotomy should be considered if the patient is unable to take ovulation-suppressing drugs, has a recurrent pneumothorax while on drugs, or wants to become pregnant. Pneumothorax complicating pregnancy is managed in the usual way, but due to the fact that there is a high rate of recurrence during parturition, thoracotomy with resection of blebs if present should be considered.²³²

PNEUMOTHORAX IN AIR TRAVELERS

The volume of gas is inversely proportional to the pressure at which it is exposed. As barometric pressure falls in the aircraft cabin during ascent, trapped air in any noncommunicating body cavity, such as in a lung bleb or bulla, will expand. Regulatory government agencies, such as the

Federal Aviation Administration, have requirements specifying that commercial aircraft cabins be pressurized to simulate an altitude (so-called cabin altitude) of approximately 8000 ft (2438 m). It is estimated that the volume of air in a noncommunicating body cavity will increase by approximately 38% upon ascent from sea level to the maximum "cabin altitude" of 8000 feet (2438 m).²³³ For patients who develop signs and symptoms of a pneumothorax in-flight, administration of supplemental oxygen is the most important intervention. For patients in respiratory distress, emergency landing at the nearest airport will allow prompt evaluation and insertion of a chest tube, if needed. The optimal length of time to wait after resolution of a pneumothorax is unknown.²³⁴ For patients with a prior pneumothorax, the decision regarding air travel must be made on an individual basis. One must take into consideration the likelihood of recurrence and how well the patient would tolerate a subsequent pneumothorax. A patient with relatively normal lung parenchyma could be permitted to fly 2 weeks after resolution of an iatrogenic pneumothorax. In a patient with severe bullous emphysema, limited cardiopulmonary reserve, and a prior spontaneous pneumothorax, air travel may be contraindicated.

CTD, chest tube drainage; ELCs, emphysemalike changes; PTX, pneumothorax. (From Noppen M, De Keukelieire T: Pneumothorax. *Respiration* 2008;76:121-127.)

PNEUMOTHORAX IN LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis (LAM) is a rare and often fatal disease that affects predominantly women of childbearing age. The normal architecture of the lung is distorted by multiple small cysts, ranging from 0.1 cm to several centimeters in diameter, with progressive decline in lung function. Spontaneous pneumothorax occurs in 50% of cases. It is often recurrent, can be bilateral, and may necessitate pleurodesis.^{235,236} Because of the morbidity and cost associated with multiple recurrences, recommendations include definitive intervention at the time of the initial pneumothorax. Pleurodesis in these cases does not preclude successful transplantation.²³⁷

COMPLICATIONS RELATED TO MANAGEMENT

Reexpansion pulmonary edema may occur after rapid reexpansion of a collapsed lung in patients with a pneumothorax. It is typically unilateral²³⁸ (Fig. 47.11). The pathophysiologic mechanism is unknown. The incidence of reexpansion pulmonary edema initially appeared to be related to the rapidity of lung reexpansion and to the severity and duration of lung collapse. However, a study examining development of reexpansion pulmonary edema following thoracentesis found that it was independent of the volume of fluid removed and pleural pressures, and recommended that even large pleural effusions be drained completely as long as chest pain or end-expiratory pleural pressure less than -20 cm H₂O does not develop.²³⁹ Patients typically present soon after the inciting event, although presentation can be delayed for up to 24 hours in some cases. The clinical course varies from isolated radiographic changes to complete cardiopulmonary collapse. Mortality rates as high as 20% have been described.²⁴⁰ Treatment is generally supportive. Supplemental oxygen is administered and, if necessary, mechanical ventilation is used. The disease is usually self-limited.

KEY POINTS

- PSP occurs primarily in tall, thin, previously healthy young men, most of whom are smokers. Chest radiograph often shows apical subpleural blebs or bullae. Rupture of these bullae is *not* related to physical activity but may be related to changes in atmospheric pressure. COPD is the most common cause of secondary pneumothorax. Presentation of pneumothorax in COPD is often atypical and causes excessive morbidity and mortality rates.
- A high incidence of pneumothorax occurs in HIV-infected patients, related to PCP and the mechanical ventilation and bronchoscopy that are commonly required in these patients. In this group of patients, pneumothorax is frequently bilateral, recurrent, and unresponsive to conservative therapy.

KEY POINTS (Continued)

- Traumatic pneumothorax, which occurs as a result of a penetrating injury, may occur with closed chest trauma.
- Pneumothorax is a common complication of mechanical ventilation. Interstitial emphysema is a harbinger of this complication. High peak and mean airway pressures, PEEP, use of volume-cycled ventilators, intubation of right mainstem bronchus, chronic airway obstruction, and aspiration pneumonia increase the incidence.
- Simultaneous bilateral pneumothoraces and “shifting pneumothoraces” are rare but interesting conditions that may develop because of persistent pleuropleural communication called *iatrogenic buffalo chest*.
- An immediate postbronchoscopy chest radiograph is rarely useful but should be done in certain groups of patients (e.g., comatose, mentally retarded, ventilated, or with respiratory compromise).
- Pneumothorax induced by a misplaced small-bore feeding tube is not uncommon. Clinical signs may be misleading.
- A visceral pleural line with absence of lung markings peripherally is the classic radiographic sign of pneumothorax. When the chest radiograph is obtained in the supine position, the signs are very different.
- Pulmonary ultrasonography is a promising technique for detection and exclusion of pneumothorax, especially in critically ill patients.
- PBT refers to alveolar rupture due to elevated transalveolar pressure. The clinical presentation can vary, ranging from absent symptoms with subtle radiographic findings to respiratory distress or cardiac arrest due to a large tension pneumothorax. Prevention is critical and limiting plateau pressures to less than 30 cm H₂O may be an effective approach.
- The approach to management of a pneumothorax is dictated by the clinical condition rather than merely the size of the pneumothorax, which is best estimated by CT scan of the chest. Expectant therapy is recommended for a small PSP in a stable patient. Reabsorption of air is hastened by 100% oxygen.
- Air can be removed by simple aspiration, a small-lumen catheter, or tube thoracostomy. Unstable patients with large secondary pneumothorax must be managed with tube thoracostomy.
- Tension pneumothorax is a medical emergency and requires a high clinical suspicion followed by prompt thoracostomy if the patient is clinically stable. However, in an unstable patient, needle decompression followed by chest tube placement may be required.
- Definitive management of recurrent pneumothorax or persistent leak can be done by open thoracotomy or video-assisted thoracoscopy associated with pleurodesis, pleural abrasion, parietal pleurectomy, or bullectomy. In patients unsuitable or unwilling for

Continued on following page

KEY POINTS (Continued)

surgery, chemical pleurodesis via a chest tube may be done.

- Pneumothorax tends to recur in patients with CF. Blebectomy, without stripping the pleura, is recommended in these patients so that they may remain transplant candidates. Pleurodesis should not be done in these cases because adhesion development jeopardizes subsequent lung transplantation.
- Pneumothorax in pregnancy is managed in the usual manner initially. In view of the high recurrence rates during parturition, thoracotomy with resection of blebs should be considered.

INTRODUCTION

EPIDEMIOLOGY

The global burden of disease represented by inhalation injuries continues to grow. Industrialization of developing nations results in increased morbidity and mortality. Inhalation injury can be defined as “an injury due to the inhalation of thermal and/or chemical irritants” and comprises both acute and chronic exposures.

Chronic exposure to inhalation of atmospheric pollution may damage the lung over decades, predisposing to infection, pulmonary fibrosis, or cancer.¹ The World Health Organization estimates that more than a billion people, mainly in developing countries, develop airway and pulmonary inflammation resulting from inhaled smoke from indoor cooking fires, forest fires, and burning of crops.² In the industrial world, chronic inhalation injury may be due to cigarette smoking or occupational exposure (e.g., asbestos). This aspect of inhalation injury will not be further discussed in this textbook, and readers are referred to other resources.³

Acute smoke inhalation results in approximately 23,000 injuries and 5000 to 10,000 deaths per year in the United States alone. Among industrial countries, the United States has one of the highest incidences of smoke inhalation injuries.⁴ The ensuing pulmonary derangements, which follow burn and smoke inhalation injuries, are major contributors to morbidity and mortality in fire victims. The pathophysiology of the injury is multifaceted and induces distant organ

dysfunction (Fig. 48.1). The consequences of the profound airway inflammation are heightened by pulmonary shunting and augmented microvascular pressure gradient, resulting in hypoxemic respiratory failure.⁵ Although survival from burn injury continues to improve, this is not mirrored in inhalation management. The acute lung injury caused by smoke inhalation and pneumonia has a major negative impact on mortality figures in patients with burn injuries. Inhalation injury alone increases mortality in burn victims by approximately 20% and pneumonia increases the rate by approximately 40%, with a maximal increase of approximately 60% when both are present.⁶ The mainstay of treatment of the smoke inhalation sufferer remains optimal respiratory support with airway toilet, adequate fluid resuscitation, early and aggressive surgical interventions, and precise antimicrobial interventions. Continued research into this systemic process is needed to stop smoke inhalation injury being the major cause of death in fire victims.⁷

HISTORY

Inhalation injuries, both of toxins and smoke, have been recorded in the history books for several thousand years and have been used with enmity from the outset. Thucydides records the Spartans burning pitch, naphtha, and sulfur to produce sulfur dioxide while attacking Athenian cities in 423 BC.⁸ The fifteenth century brought incendiary devices filled with sulfa and belladonna.⁹

The history of toxic gases other than smoke tends to run hand in hand with military conflict, and it wasn't until the

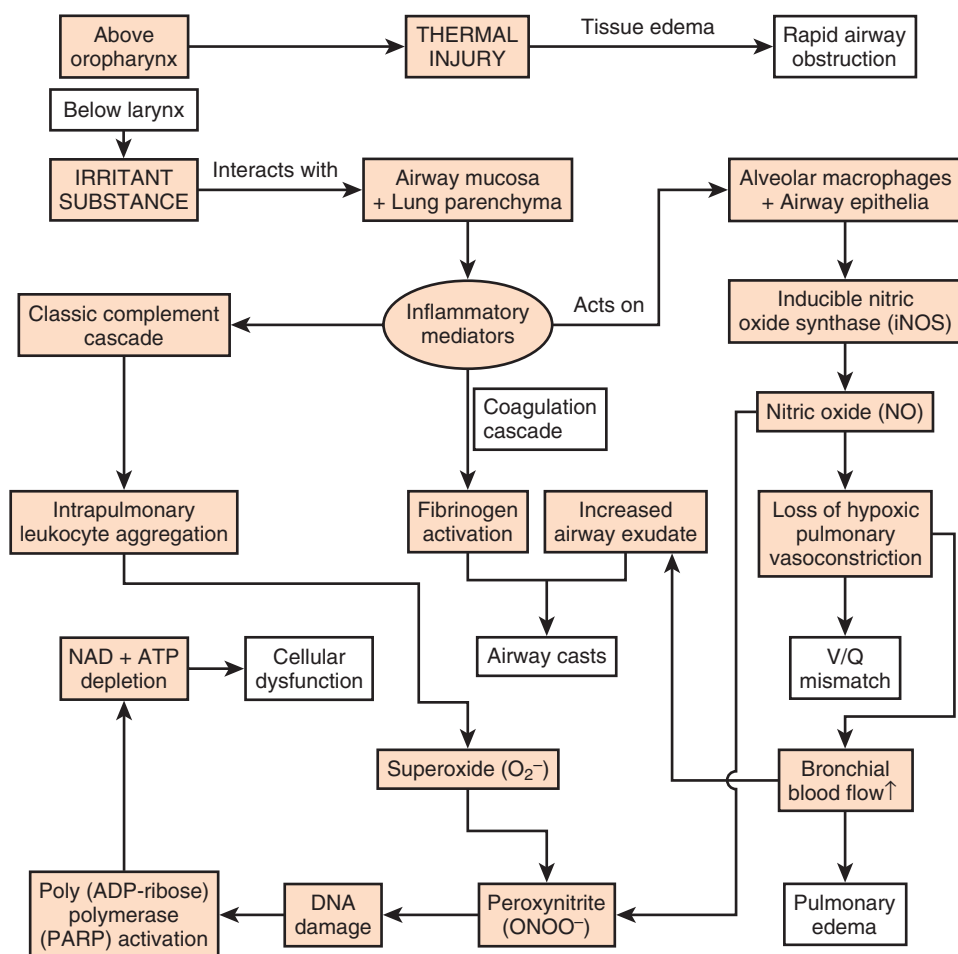

Figure 48.1 Pathophysiology of acute smoke inhalation injury.

First World War that the increased usage sparked off once more, where at least 14 different toxic respiratory agents were used. The years 1914-1915 marked the modern nascence of inhalation warfare when France released chloroacetone and Germany released thousands of liters of chlorine gas in Belgium, at Ypres. More than 1 million casualties were attributed to the use of chemical agents during that war, with sulfur gas being anointed as the “king of battle gases.”¹⁰

The 1925 Geneva Protocol signed by many countries pledged never to use gas warfare again.⁹ Sadly, this has not been adhered to, with Italy being accused of using mustard gas against Abyssinia in Ethiopia. The Chinese suffered gas inhalation at the hands of the Japanese during the Second World War, and the Kurds were victim to similar agents during the attacks by Iraq through the 1980s.¹¹ Sarin gas poisoning was used in Japan in the mid-1990s. In 1994 and 1995, inhaled biochemical weapons have been used for terrorism acts like the sarin gas attacks in Japan.¹² Cyanide (CN) may be considered one of the most likely agents of chemical terrorism, as it is capable of causing mass incapacitation and casualties and can cause mass confusion, panic, and social disruption. In addition, cyanide possesses all attributes of an ideal terrorist weapon: it is plentiful, readily available, and easily obtainable because of its widespread use in industry and laboratories.¹³ Although military interest in biochemical warfare diminished following World War II,

there was an understanding of the devastation possible with nuclear weapons; terrorist organizations understand the fear, panic, and collapse of infrastructure that could be realized through the release of such a substance in a busy city. It seems likely that there are many areas of the world where such agents are, or can be, manufactured in great quantities.⁹

Equally, smoke inhalation has a long record in history, with the first recording by Pliny in the first century AD. He described the execution of prisoners over greenwood smoke, and it seems he may have died through toxic smoke inhalation himself during the eruption of Vesuvius in 79 AD. More recently, two much more industrial occurrences highlighted the problems of smoke inhalation. The Cocoanut Grove fire of 1942 resulted in the deaths of 491 people who were trapped in a burning building. The number of patients who sustained burns was minimal, and it was then that the realization hit that smoke alone could kill as easily, if not more so, than cutaneous burns.¹⁴ More than 2000 burn/smoke casualties resulted after the chain of fires and explosions that rippled through refineries and factories in Texas City, Texas, in the 1940s.¹⁵ The understanding of smoke and carbon monoxide (CO) inhalation in enclosed spaces was further highlighted in the fire at the MGM Grand Hotel in Las Vegas in 1980 and the Stardust Nightclub fire in Dublin in 1981. Again, the small number of burn injuries was swamped by the deaths resulting from smoke and CO.¹⁶

Cyanide's independent role became clear in the 1980s, particularly after the aircraft fire at Manchester International Airport, Manchester, UK, in 1985 where the majority (87%) of the 54 individuals who died had potentially lethal levels of cyanide in their blood, as opposed to only 21% of these victims having carboxyhemoglobin (COHb) levels exceeding 50%. This event highlighted that different combustants produce different inhalants, and depending on the environment, these may be more lethal than carbon monoxide, which had been regarded as the primary toxic threat.⁴ Hence, the determinants of inhalants are both environment and material being combusted. It is therefore a mixed toxicology following smoke inhalation.

The terrorism attacks on September 11, 2001, on the World Trade Center in New York were associated with a high incidence of inhalation injuries. Among the 790 injured survivors, 49% suffered from inhalation injury caused by toxic compounds in the smoke and dust.^{17,18} Industrial catastrophes, biochemical warfare, and terrorism will continue to occur. This chapter's aim is to help physicians diagnose and then manage patients with inhalation injuries.

PATHOGENESIS OF INHALATION INJURY

TOXIC SMOKE COMPOUNDS

Smoke is a heterogeneous compound. Each fire produces different toxic features relating to the material combusted and the environment in which the fire occurs, specifically oxygen content. Hence, each patient suffering smoke inhalation may represent a new condition with a possibility of many different inhalants.¹⁹ The components of smoke that cause damage are as follows:

- Heat.
- Particulates, deposited in the airways according to their size, with substances smaller than 1 μm in diameter able to reach the alveolar zone suspended in air. At that site, these chemically laden particles increase airway resistance and cause cell lysis and irritation while diminishing pulmonary surfactant production and efficacy.¹⁹
- Systemic toxins, such as carbon monoxide and cyanide, which adversely affect oxygen transport by erythrocytes and utilization by mitochondria.²⁰
- Respiratory irritants are implicated in the high mortality rates. Water-soluble gases such as ammonia and hydrogen chloride react with water contained in mucous membranes and produce strong alkalis and acids, which elicit profound inflammatory reactions, which rapidly induce systemic changes via the dense alveolar-capillary interphase. Lipid-soluble irritants (e.g., oxides of nitrogen, phosgene, and aldehydes) exert their effects more slowly as they dissolve into the cellular membrane.²¹

HEAT

Burns to the nasal and oropharyngeal mucosa are common in fire-exposed victims, but it is rare to encounter thermal injury below the vocal cords. This is because the oropharynx acts as an effective "heat sink," with the thermal energy of the heated air dissipating into the cells they pass by, causing

Figure 48.2 Swollen hyperemic epiglottis and narrowed laryngeal opening.

rapid cell injury, necrosis, and swelling of the upper airway (Fig. 48.2). This can result in upper airway obstruction, which can be fatal before the sequelae of pulmonary burn become apparent. Super-heated steam is an exception, where the oropharynx cannot absorb all the thermal energy, and hence airway burn occurs in this situation.²²

SYSTEMIC TOXINS

Systemic toxins are products of incomplete combustion and include carbon monoxide and hydrogen cyanide. Carbon monoxide intoxication, together with heat incapacitation and a hypoxic environment, is the most common immediate cause of death from fire.²⁰ Carbon monoxide is an odorless, colorless gas that binds to erythrocyte hemoglobin with about 250 times the affinity of oxygen. The resulting COHb molecule is unable to transport oxygen, thus impairing oxygen delivery to the tissue and shifting the oxygen-dissociation curve to the left.²³ Furthermore, at the tissue level, carbon monoxide competes with, and inhibits, oxygen binding to the cytochrome oxidase system of enzymes, inhibiting the aerobic metabolism chain and thus incapacitating cellular respiration.²¹ Hence, CO paralyzes oxygen carriage in the blood and subsequent utilization in the tissue (see Table 48.2, presented later in the chapter). Thermal decomposition of nitrogen-containing polymers in oxygen-poor environments produces smoke containing hydrogen cyanide, inhibiting electron transport and cellular respiration.¹⁹

AIRWAY INJURY

Although the inhaled gases as described earlier can cause significant and fatal alterations in physiology, the chief mediator of the pathophysiology of smoke inhalation is particulate matter. Carbonaceous particles (soot) impregnated with a multitude of toxins reach the alveolar level suspended in air.²⁴ The chemicals associated with these particles vary depending on the products combusted but commonly include aldehydes from cellulose-based materials such as wood and paper; nitrogen oxides from fabric combustion;

halogen acids and sulfur dioxide from rubber; ammonia from wool, silk, and polyurethane; and phosgene from polyvinyl chloride.²² Water-soluble compounds are readily soluble in airway mucus and interact freely with tissue at more proximal levels of the respiratory system. Less water-soluble compounds (such as phosgene) penetrate the airway mucosa deeply and may cause severe delayed damage through late interaction with distal airway tissues, up to 48 hours after exposure. This is an important consideration when treating patients who initially present with apparently mild clinical effects after smoke inhalation.²²

PULMONARY PARENCHYMAL INJURY

Although thermal injury is mostly adsorbed in the upper airway, the other components of smoke—particulate materials, systemic toxins, and respiratory irritants—descend to the lung and trigger a cascade of events, resulting in pulmonary edema, bronchiolar obstruction, cell death, and ventilation/perfusion (V/Q) mismatch.¹⁹

Of paramount importance is the cascade of inflammatory mediators activated by the interaction of irritant substances with the airway mucosa and lung parenchyma. Intrapulmonary leukocyte aggregation following activation of the classic complement cascade releases even more chemokines and cytokines, leading to the production of free radicals of oxygen and nitrogen²⁵ from nitric oxide synthase (NOS)–triggered nitric oxide (NO) and peroxynitrite (ONOO[−]) production. The vasodilation induced by NO rapidly increases bronchial blood flow and decreases the degree of the protective hypoxic pulmonary vasoconstriction in poorly ventilated areas of the lung, resulting in V/Q mismatch.²⁶ This also intensifies the spread of irritants from the pulmonary to systemic circulation. NO also combines with superoxide (O₂[−]) produced in large quantities by activated neutrophils to form ONOO[−]. This reactive nitrogen species leads to DNA damage and subsequent activation of poly (Adenosine diphosphate ribose [ADP-ribose]) polymerase, an important enzyme in DNA repair. This activation and subsequent action requires a large amount of chemical energy in the form of adenosine triphosphate (ATP) and Nicotinamide adenine dinucleotide (NAD), the depletion of which causes necrotic cell death of deprived energy-dependent tissues.²⁵ The combination of these effects contributes to tissue injury and increased pulmonary vascular permeability, leading to decreased diffusion, edema, and V/Q mismatch. Furthermore, neutrophils are sequestered from the systemic circulation to the intrapulmonary compartment and are activated, and fibrinogen release by inflammatory mediators causes airway cast formation and widespread plugging. These casts obstruct a number of the smaller airways, and subsequent efforts to mechanically ventilate this inhomogeneous lung can induce ventilator-induced barotrauma as normal lung is overdistended, whereas other regions collapse, and atelectasise. The further tissue injury is heightened with biotrauma of ventilation, and the production of chemokines leads to a potent accumulation of damage.²¹

Much of the study of smoke inhalation injuries in animal models has focused on aspects of this pathophysiologic sequence. Attempts to manipulate and alter the chain of effects experimentally have reinforced these theories

and suggested exciting treatment targets. Nevertheless, experimental treatments have yet to deliver specific therapeutic modalities that improve the course of smoke inhalation injury.⁵

DIAGNOSTICS AND TREATMENT

INITIAL PREHOSPITAL RESCUE

The first priority at the injury scene is rescue of the victim from the source of fire to minimize the exposure time. This is usually the responsibility of firefighters.⁴ The patient must be assessed as a trauma patient and not merely as the victim of an isolated burn or smoke inhalation injury. Standard early management of severe trauma (EMST) protocols must be observed, including stabilization of the neck. Following the immediate administration of a high flow of O₂ to reduce COHb levels, a primary survey must then follow to assess accompanying injuries such as burns or trauma with simultaneous estimation of the extent of smoke inhalation. In addition, it is important to determine whether the victim has been exposed to an explosion and to assess the possibility of blast injury to the lung. If possible, information about comorbidities should be obtained. Standard cardiopulmonary monitoring (electrocardiogram, pulse-oximetry, and noninvasive blood pressure) and intravenous access should be established.²⁷ Carbon monoxide poisoning can result in an erroneously high SaO₂ reading due to the light absorption of the classic “cherry red” hemoglobin in smoke inhalation. After these basic measures, the safety of the airway must be assessed. The risk of rapidly developing airway edema has to be taken into account even if no dyspnea is present, but it must be balanced by the real risks faced by endotracheal intubation itself in an unstable, potentially hypoxic patient with possible neck injuries. In the authors’ opinion, endotracheal intubation that is entirely prophylactic is ill advised. Nevertheless, the airway with early edema is likely to worsen, particularly if significant fluid resuscitation is required for burn injury, and hence repeated and thorough assessment of the airway is mandatory. Patients with evidence of stridor or heat and smoke inhalation injury combined with extensive face or neck burns may mandate early intubation. In the case of oral burn without inhalation injury, an airway secured early represents the safest approach. However, victims with smoke inhalation injury but no facial or neck burns can be carefully observed and can be intubated later, if necessary.²⁸ The patient’s head should be elevated to 45 degrees to minimize facial and airway edema. In the field, fluid resuscitation can be minimized to reduce the risk of airway compromise if the necessary skills or equipment are not readily available for intubation. Nebulized adrenaline or corticosteroids may be used in the hope of minimizing upper airway edema, although there is no conclusive evidence for the efficacy of these treatment strategies.²⁹ Bronchospasm is frequently observed, and the nebulized administration of bronchodilators, such as β_2 -agonists, will reduce this effect, while improving respiratory mechanics by decreasing airflow resistance and peak airway pressures in ventilated patients. This results in improved dynamic compliance. In addition, β_2 -agonists provide anti-inflammatory properties, represented by a decrease in inflammatory mediators such as

histamine, leukotrienes, and TNF- α . Finally, β_2 -agonists are associated with improved airspace fluid clearance and stimulation of mucosal repair.³⁰⁻³²

After initial stabilization of the patient, information about the type of fire and combustible materials involved, whether the fire occurred in an enclosed space, and the estimated duration of exposure should be sought. In cases of presumed specific intoxication, appropriate therapies should begin.²¹ Diagnosis of such intoxications is impossible in the field, but a high degree of suspicion must be maintained if the combustion materials and enclosed space lead the treating practitioner to assume risk of CO or CN. All patients should be immediately administered 100% O₂ from a high-flow facemask to reduce the CO binding to Hb. Specific therapies exist to treat the toxicity of carbon monoxide and cyanide, which aim to reduce the serum levels of these substances. Depending on the Glasgow Coma Scale, the severity of injury, and the symptoms, the patient's condition may mandate intubation and mechanical ventilation with an Fio₂ of 1.

Patients with the possibility of cyanide intoxication require standard supportive care, which may be augmented with specific antidote therapy—the choice of which is the more efficacious remains controversial. Amyl nitrate and sodium thiosulfate are used to oxidize hemoglobin to methemoglobin, which preferentially binds cyanide. In contrast to these antidotes, hydroxycobalamin (vitamin B12a) actively binds CN by forming cyanocobalamin, which is directly excreted via the kidney. Because it does not produce methemoglobin, hydroxycobalamin is safe to use in the preclinical setting. Accordingly, it represents the active compound of the “Cyanokit,” which is used in the prehospital management of smoke inhalation injury in Europe with a reported reduction of mortality³³ (Table 48.1).

AIRWAY MANAGEMENT

Clinical suspicion of inhalation injury of the upper airway is aroused by the presence of certain risk factors such as history of exposure to fire and smoke in an enclosed space or a period of unconsciousness at the accident scene, burns including the face and neck, singed facial or nasal hair, altered voice, dysphagia, oral or nasal soot deposits, or carbonaceous sputum. The most immediate threat from inhalation injury is upper airway obstruction due to edema (see Fig. 48.2). Early intubation is recommended when this complication threatens and the patient was not intubated on scene.³⁴ However, exposure to smoke does not always lead to severe injury, and in the absence of overt evidence of respiratory distress or failure it may be difficult to identify patients who will experience progressive inflammation and ultimately require intubation of the trachea. When intubating in the field, optimal technique to secure a difficult airway is a contentious issue. Experienced operators may attempt to preserve spontaneous breathing, which allows patients to maintain their own reflexes even when intubation is not possible. Others may elect to perform a rapid sequence induction, which provides better intubating conditions but oblates all of the patient's own airway reflexes. Attention should be given to gastric residuals during enteric feeding after admission to the burn intensive care unit. In addition, the development of sepsis can slow gastric

Table 48.1 Treatment Strategies for Acute Smoke Inhalation

Current	Under Investigation
Rescue victim from source	Activated protein C
High flow 100% O ₂	Anti-inflammatory drugs <ul style="list-style-type: none"> — Methylprednisolone — Phenytoin
Body check	Nitric oxide synthase inhibitors
Intravenous access	Antioxidants <ul style="list-style-type: none"> — Gamma-tocopherol — 21-aminosteroid
± Intubation	Endothelin-I-receptor antagonist tezosentan
If upper airway edema: <ul style="list-style-type: none"> — Nebulized adrenaline — Nebulized corticosteroids 	P-selectin blockade
If bronchospasm: <ul style="list-style-type: none"> — Nebulized alpha2-agonists 	Nebulized deferoxamine-pentastarch complex
If elevated COHb: <ul style="list-style-type: none"> — High-flow 100% O₂ — Hyperbaric oxygen 	Mechanical ventilation <ul style="list-style-type: none"> — High-frequency percussive ventilation — Airway pressure release ventilation — Volumetric diffuse ventilator
If cyanide intoxication: <ul style="list-style-type: none"> — Amyl nitrate — Sodium thiosulfate — Hydroxocobalamin Cyanokit 	Extracorporeal membrane oxygenation
Mechanical ventilation	Arteriovenous carbon dioxide removal
Low tidal volume	Pulmonary decontamination with nebulized amphoteric chelating agents
Nebulized heparin	
Nebulized <i>N</i> -acetylcysteine	

Table 48.2 Carboxyhemoglobin Concentration and Related Symptoms

COHb [in %]	Symptoms
<20	Slight headache and dilation of peripheral blood vessels
21-40	Severe headache and pulsating in temporal blood vessels, vertigo, dizziness, nausea and vomiting, circulatory collapse
41-60	Symptoms as above, syncope, tachycardia, hyperventilation, intermittent seizures, cyanosis, coma, shock, Cheyne-Stokes respiration
61-80	Coma, intermittent seizures, impaired heart and lung function, weak pulses, slow breathing, death within hours
>81	Death occurs within minutes

emptying, which can result in retained fluids in the stomach and risk of aspiration.²⁷

A patient with a compromised airway has evolved to maintain the airway at all costs. This primitive survival instinct is neutered if paralyzing agents or heavy sedation is administered and the safe airway can rapidly become unsalvageable. Intubation of a spontaneously breathing patient, while being more technically challenging, is safer, as the patient will keep breathing at all costs. In terms of anesthetic airway management, the most profound and clinically significant effect of burn injuries on drug response relates to muscle relaxants. Burn injuries influence responses to both succinylcholine and the nondepolarizing muscle relaxants. In burned patients, sensitization to the muscle relaxant effects of succinylcholine can produce exaggerated hyperkalemic responses severe enough to induce cardiac arrest, though this tends to occur 24 to 48 hours post injury, rather than immediately.³⁵ However, recommendations regarding the safe use of succinylcholine after burn injury cannot be given. Various authors recommend avoidance of succinylcholine at intervals ranging from 24 hours to 21 days post burn injury,³⁶ but it seems clear that the hyperkalemic response associated with burn does not occur in the first day and hence the drug can be used with standard precautions at this stage.

An increase in the numbers of acetylcholine receptors and the proliferation of these receptors away from the neuromuscular junction have been suggested as common mechanisms explaining both reduced sensitivity to nondepolarizing relaxants and the exaggerated hyperkalemia that may follow succinylcholine administration in burned patients. Resistance is apparent by 7 days post injury and peaks by approximately 40 days. Sensitivity returns to normal after approximately 70 days. In contrast to other nondepolarizing neuromuscular blockers, mivacurium dosage requirements in pediatric patients appear to be unchanged by burn injury.³⁷

Preoxygenation may be more difficult in the smoke inhalation victim, and relative loss of mandibular mobility may impair airway manipulation, making bag-mask ventilation difficult. The swelling and distortion of the mouth and mandibular aspect of the airway may make preoxygenation and direct laryngoscopy difficult or impossible. Preoxygenation with small aliquots of anxiolysis and analgesics (such as 0.5- to 1-mg increments of midazolam and 25- to 50- μ g boluses of fentanyl IV) with sequential direct spraying of lignocaine to the oropharynx and then subsequently under direct vision of the larynx/epiglottic area is technically difficult but safe in experienced hands. Fiberoptic intubation with nebulized or directly sprayed lignocaine spray while maintaining spontaneous ventilation is equally safe but requires a substantial level of skill with the bronchoscope. However, pediatric patients are unable to cooperate and must be adequately sedated. Because deep sedation and full anesthesia cause collapse of pharyngeal tissues and airway obstruction, they are unsuitable for fiberoptic intubation in patients whose airway would be difficult to manage with a mask.³⁸

Agents that may prove useful to facilitate fiberoptic intubation include the ultra-short-acting remifentanyl. The novel α -2-adrenergic agonist dexmedetomidine, which provides sedation, anxiolysis, and analgesia with much less respiratory depression than other sedatives,³⁹ may be

considered, though further data are required until its widespread use is adopted. Ketamine remains a very useful drug, as it provides some analgesia and facilitates a degree of spontaneous breathing while allowing dissociative anesthesia. However, airway secretions may be copious and the clinician must always be aware of this.

Securing an endotracheal tube in a patient with facial burns presents a variety of problems. Tape or ties across damaged or grafted skin can worsen tissue loss or induce graft failure. A useful technique to avoid these problems involves the use of a nasal septal tie.

The use of a laryngeal mask airway (LMA) has also been successful for airway management during burn surgery for children.⁴⁰ In the acute phase or in the intensive care unit, the LMA serves as a rescue device when endotracheal intubation fails, but it must be replaced with a definitive airway as soon as is practically possible, as gastroparesis is common in the burn patient.

MONITORING AND INVESTIGATIONS

Damages to the airway and lung from inhalation injury often develop with a latency of several hours and are affected by other injuries and degree of fluid resuscitation required. Nevertheless, airway management and the oxygenation status of the patient, regardless of intubation status, need to be frequently reevaluated; such is the dynamic nature of smoke inhalation injury.²² After stabilization of cardiopulmonary hemodynamics and pulmonary gas exchange, the assumed diagnosis of smoke inhalation injury needs to be verified. However, as no uniform criteria are available, diagnosis of smoke inhalation injury has a subjective component based on history, physical examination with supporting imaging, and blood gas assays. Bronchoscopic examination of the airway represents the gold standard to detect a pathognomonic mucosal hyperemia with soot staining below the larynx being diagnosed (Fig. 48.3). Although chest radiographs are mandatory and may reveal injuries consistent with trauma—that is, fractured ribs, pneumothorax, and pulmonary contusion—they provide little information acutely as to the degree of smoke inhalation. Specific changes that may be seen related to the smoke inhalation

Figure 48.3 Soot staining in the hyperemic trachea.

include signs of diffuse atelectasis, pulmonary edema, or bronchopneumonia.⁴¹

A uniform algorithm for assessing inhalation injury or a reliable indicator of progressive respiratory failure in patients with smoke inhalation injury has not yet been established. This failure is largely explained by the extreme heterogeneity of the clinical presentation. In addition, the delay in the manifestation and development of acute lung injury (ALI) as a consequence of systemic inflammatory response syndrome (SIRS), initiated by accompanying burns or trauma, complicates the evaluation of the isolated effects of smoke inhalation. Frequent blood gas and sputum analyses are useful to monitor patients with smoke inhalation injury.²⁸ In addition, inexplicably high lactate levels, despite adequate fluid resuscitation, will be helpful for the diagnosis of CN poisoning. In a study by Pham and colleagues,⁴² cyanide poisoning in the canine model showed two phases of injury. The first (compensated) phase had a mechanism consistent with a traditional global oxygen consumption defect. The second (decompensated) phase had a mechanism consistent with heart failure. This heart failure was due to bradycardia. The systolic blood pressure remained relatively constant, whereas diastolic blood pressure decreased by 19%. Cardiac output, heart rate, and DO_2 increased to a maximum of 6%, 10%, and 10%, respectively, at 40 minutes, after which they declined to a low of 32%, 28%, and 30% below baseline, respectively. Stroke volume remained constant. Oxygen consumption initially increased by 5% and then decreased to 24% below baseline. The oxygen extraction ratio (OER) initially declined to 35% below baseline and then increased throughout the rest of the study. In clinical practice, serial venous blood gases may unmask cytopathic hypoxia, by insufficient O_2 extraction, that may be seen as increased central venous (ScvO_2) or mixed venous (SvO_2) oxygen saturations.

FLUID RESUSCITATION

Optimal fluid management is critical to the survival of the victim of a major thermal injury, with additional or isolated inhalation injury, and when septic complications occur. Modern fluid resuscitation formulas originate from experimental studies in the pathophysiology of burn shock. Fluid resuscitation in the patient with thermal injury has been recognized as an essential aspect of the care since the first studies were published in 1905.⁴³ The improvement in outcome with cutaneous burns can be related to the development of a protocol based on providing adequate fluid resuscitation to allow optimal organ function while minimizing the physiologic cost associated with over-resuscitation.

Burn shock is both hypovolemic shock and cellular shock and is characterized by specific hemodynamic changes including decreased cardiac output, extracellular fluid, plasma volume, and oliguria. As in the treatment of other shock forms, the primary goal is to restore and preserve tissue perfusion in order to avoid ischemia. However, in burn shock, resuscitation is complicated by obligatory burn edema, and the voluminous transvascular fluid shifts that results from a major burn are unique to thermal trauma.⁴⁴ Blalock may have been the first to postulate the mechanism, where he induced burn to one side of mongrel dogs and assessed the weight changes in both burned and unburned

tissue, demonstrating that burn tissue edema correlated to the drop in blood pressure and was similar in composition to plasma.⁴⁵ Although the exact pathophysiology of the post-burn vascular changes and fluid shifts is still unclear, major components of burn shock are the increase in total body vascular permeability and the changes in microcirculation. Fluid resuscitation is aimed to support the patient throughout the initial 24-hour to 48-hour period of hypovolemia and has existed since the early 1950s.

Cope, in his seminal paper following the Cocoanut Grove disaster, was the first to report the increased fluid requirement seen in patients with smoke inhalation injury.⁴⁶ This observation has been confirmed by multiple other papers, despite the lack of thermal injury below the larynx; hence fluid loss seems unlikely. One theory, which concurs with much of the known pathophysiology, relates to inflammatory excess seen postsmoke inhalation. Approximately 28% of all neutrophils reside in the human lungs, and this percentage increases postinhalation insult. As described earlier, it is well recognized that the particulate and chemical nature of inhalation injury induces neutrophil activation and the release of numerous cytokines, proteases, and free radicals. This further recruits neutrophils from the systemic circulation, and the local inflammatory state rapidly becomes systemic due to the vast alveolo-capillary interphase transporting these mediators and modulators of vasodilatation to distant organs. The up-regulation is not only in number but also in responsiveness to endotoxin.^{21,47} Regardless of mechanism, numerous authors have reported that smoke inhalation per se increased the fluid requirement substantially.⁴⁸⁻⁵⁰

Although under-resuscitation in thermal and smoke inhalation injury is known to induce organ failure and death, there are growing concerns with over-resuscitation, where the “fluid creep” can induce increased extravascular water content, resulting in compartment syndrome in extremities or in the abdomen.⁵¹ Even after thousands of patients have been saved by fluid resuscitation, resuscitation formulas are still controversially discussed, depending on advantages and disadvantages for the individual patient. Crystalloid solutions, such as lactated Ringer’s solution (sodium concentration 130 Meq/L), are the most popular resuscitation fluids currently utilized. Crystalloid formulas are the “Parkland formula” (which recommends 4 cc/kg/% total body surface area (TBSA) burn in the first 24 hours, with half of the amount administered in the first 8 hours) and the “Modified Brooke formula” (which recommends 2 cc/kg/% TBSA burn). Colloid formulas (Evans, Brooke, Slater), the Dextran formula (Demling), and hypertonic saline formulas (Monafo, Warden) are also in use.^{44,52-54}

Concerns with colloid administration in the resuscitation of early burns began with Goodwin’s work in the 1980s,⁵⁵ where it was suggested that there was a lack of benefit over crystalloid and potential pulmonary harm, and grew substantially in the late 1990s, but more recent work suggests that concerns of increased capillary leak particularly in the lungs are overplayed, and the pendulum seems to be swinging back toward the judicious use of colloid to minimize the risk of abdominal compartment syndrome (ACS). A randomized controlled trial (RCT) by O’Mara compared plasma to crystalloid in burn resuscitation and showed that colloid resulted in less ACS but no demonstrable improvement in outcome.⁵⁶

Early studies in fluid resuscitation post smoke inhalation suggest a mean fluid requirement of 5.8 mL/kg/% TBSA burn for optimal outcomes, but more recent studies suggest the figure may be lower than originally expected.⁴⁹

Hypertonic salt (HTS) solutions have been known for many years for effectiveness in the treatment of burn shock by fluid sparing effects and a reduction of volume load in the early phase of injury.⁵⁷ Rapid infusion leads to serum hyperosmolality and hypernatremia, reducing the shift of fluids from intravascular to interstitial areas, which may prevent edema formation and the need for escharotomy.^{58,59} The use of HTS, however, is controversial because although there may be beneficial effects, other studies have demonstrated an increase in mortality with HTS treatment of major burns.⁶⁰

Part of the dubiety regarding the exact volume required relates to the lack of consensus of scoring severity of inhalation injury. The extent of cutaneous burn can be readily assessed. Such a scoring system for inhalation injury is lacking, and inhalation can be mild moderate or severe. In a 3-year retrospective review by Gamelli's group, numerous demographic and injury-related factors, including bronchoscopic scoring, failed to determine which patients with inhalation injury required increased fluid resuscitation. From its 80-patient cohort, the group postulated that a P_{aO_2}/F_{iO_2} ratio of <350 may be the best early determinant of which patients would require excess fluid resuscitation.⁶¹

In addition to hypovolemia, the risk of infection in smoke inhalation patients is extraordinarily high. Shirani and coworkers⁶ have shown that inhalation injury alone increased the mortality of burn patients by a maximum of 20%, and pneumonia by a maximum of 40%, with a maximum increase of approximately 60% when both are present. These data indicate that inhalation injury with additional septic complications such as pneumonia has significant, independent, additive effects on burn mortality and that these effects vary with age and burn size. The presence of inhalation injury and sepsis increases the fluid requirements for resuscitation from burn shock after thermal injury.⁴⁸ Chen and coworkers⁶² have demonstrated that HTS confers beneficial effects on burn shock, reduces bacterial translocation, and enhances host defenses by several mechanisms in the treatment of burn shock and sepsis. It is of high interest to further investigate HTS in animal models and later on in humans. Future studies with HTS alone and in combination with already established resuscitation formulas are needed to find a risk/benefit ratio for such a treatment. HTS may have the potential to improve resuscitation strategies and outcome in burn care, but it cannot be recommended at the present time due to a lack of evidence.⁶³

Despite the treatment of septic complications following inhalation injury, the gradual shift toward less fluid in both burn and smoke inhalation may relate to the changes in the intensive care unit (ICU) modalities of care—including point-of-care devices to assess oxygenation, less injurious ventilation, and more rapid debridement of burn tissue.⁶⁴

Debates and ongoing research on fluid resuscitation may last for decades, but they are needed to improve outcomes in this patient population. However, in the authors' experience it is worthwhile to start fluid resuscitation using the "Modified Brooke formula" (which recommends 2 cc/kg/% TBSA burn) to closely monitor urine output (0.5 to

1 cc/kg/h recommended) and to increase fluid administration up to a rate that will maintain the recommended urine output. This strategy may prevent initial over-resuscitation in many patients, decreasing edema formation, and will suit the increased needs of patients with inhalation injury who may need up to 6 to 8 cc/kg/h to maintain adequate organ perfusion. Excessive fluid administration beyond a urine output of 1 cc/kg/h is ill advised.

Although protocols should not be abandoned, a routine and recurrent assessment of the patient with inhalation injury would be essential to minimize physiologic injury as a result of fluid resuscitation, whether too little or too much.

TREATMENT OF CARBON MONOXIDE INTOXICATION

Current treatment recommendations of CO poisoning begin with cessation of exposure, immediate administration of 100% oxygen, and supportive care.⁶⁵ The rationale of hyperbaric oxygenation therapy (HBOT) is based on its ability to rapidly displace CO from hemoglobin, thus reducing the duration of the hypoxemic state. Administration of 100% oxygen at 3 atmospheres reduces the CO half-life from 250 minutes in room air to 30 minutes.²⁸ Besides this efficiency, its use remains controversial due to the questioned correlation between COHb levels and outcomes. This may also be explained with limited access to the patient during HBOT, which has major impact on the treatment quality of combined burn injuries.²⁸ A Cochrane database review of six randomized controlled trials did not reveal a beneficial effect of HBOT compared to standard treatment in respect to neurologic sequelae.⁶⁶ However, the results should be interpreted with care, as concerns have been raised regarding design and analyses in all the included trials. In summary, all patients with CO intoxication should be immediately treated with 100% oxygen. Although data do not support its routine use, HBOT may be considered in stable patients with severe neurologic symptoms and high COHb concentrations (>50%), but no major burns and severe pulmonary injury.⁴⁷

TREATMENT OF CYANIDE INTOXICATION

Hydrogen cyanide in fire smoke is an underappreciated threat and one of the most common poisonings in patients who suffer smoke inhalation.⁶⁷ Its lipophilicity and lack of dissociation allow it to penetrate through mucous membranes with ease, resulting in a myriad of symptoms within minutes, and possible death if the dose is large enough.⁶⁸ Patients may describe a burning, dry throat with inexplicable feelings of anxiety. Clinical signs range from a patient presenting with tachypnea, confusion (and the classic almond breath fetor) to unconsciousness, cardiovascular collapse, and death, generally from respiratory arrest (see Table 48.3).²⁰ The key for the receiving clinician is to have a high index of suspicion in such a patient, as there is no immediately available lab test. Blood gas analysis may reveal an inexplicably high lactate in the absence of CO poisoning or other trauma. However, CN poisoning frequently coexists with significant CO poisoning, and hence may be overlooked.^{4,69} For adequate treatment of CN poisoning

Table 48.3 Hydrogen Cyanide Concentration in Air and Related Symptoms

HCN [ppm]	Symptoms
0.2-5	Odor threshold
10	Occupational exposure limit
18-36	Slight symptoms, headache
45-54	Will be tolerated for 30-60 minutes
100	Death within 1 hour
110-135	Death within 30-60 minutes
181	Death within 10 minutes
280	Immediate death

following smoke inhalation injury, several antidotes are available: The “CN antidote kit” includes amyl nitrite, thio-sulfate, and sodium nitrite.⁷⁰ Because these substances are methemoglobin generators, which may additionally impair oxygen transport, they should be only used in case of proven diagnosis (increased plasma levels of CN) and under continuous monitoring in the intensive care unit, particularly in episodes of poisoning with CO simultaneously.²⁸ Methemoglobin chelates CN to form cyanmethemoglobin. As cyanmethemoglobin dissociates, free CN is converted to thiocyanate by liver mitochondrial enzymes (rhodanese) using thiosulfate as a substrate. Thiocyanate is then excreted into the urine.⁷¹ In contrast to these antidotes, hydroxocobalamin, a vitamin B12 derivative, actively binds CN by forming cyanocobalamin, which will be directly excreted by the kidneys.³³ Data are growing regarding the safety and efficacy of hydroxocobalamin. Prospective observational studies reveal that empiric administration of hydroxocobalamin was associated with survival among 67% of patients who were confirmed post administration to have had cyanide poisoning. A randomized controlled trial in pigs assessed the efficacy of hydroxocobalamin versus sodium thiosulfate in the treatment of acute cyanide toxicity. The study indicated that in severe poisoning (CN administered to hypotension to 50% of baseline blood pressure), hydroxocobalamin was safe, efficacious, and resulted in much improved survival. Worryingly, sodium thiosulfate failed to reverse cyanide-induced shock. The authors concluded that only hydroxocobalamin was effective.⁷² In case of intoxication with 1 mg CN, the recommended dose is 50 mg/kg hydroxocobalamin.⁷³ Because of the avoidance of methemoglobin production, hydroxocobalamin can be used safely in the preclinical setting. Accordingly, hydroxocobalamin represents the active compound of the “Cyanokit,” which is used in the prehospital management of smoke inhalation injury in Europe with a reported improvement in mortality.³³

Aggressive restoration of cardiopulmonary function augments the hepatic clearance of CN via the enzyme rhodanese and has been reported to be successful in severe CN poisoning (blood levels 5.6 to 9 mg/L) as well as after ingestion or smoke inhalation, even without the use of antidotes.⁷⁴⁻⁷⁶ Hydroxocobalamin has been used safely and successfully by emergency personnel in out-of-hospital settings and may represent a new option in cases of suspected or confirmed cyanide poisoning in the field.⁷⁷ Therefore, the standard care of CN poisoning should combine the

aggressive supportive therapy with current data supporting the use of hydroxocobalamin as the optimal specific therapy.⁴⁷

BRONCHOSCOPY

Within each burn center, diagnostic as well as treatment options are determined by the availability of resources (such as 133Xe scans, fiberoptic bronchoscopy, or 24-hour/day anesthesia staff coverage) and local tradition. A clear diagnosis proving smoke inhalation has occurred allows for the planning and delivery of therapeutic interventions.⁴¹ Inhalation injury can be diagnosed with confidence based on clinical presentation and bronchoscopic findings. Changes observed with bronchoscopy include erythema, lesion, erosion, ischemia, or necrosis of the mucous membrane, as well as small to significant edema, blisters, and unidentified damage of the lung parenchyma when the changes in the lower respiratory tract are below the reach of the fiberoptic scope, which can be used for inspection of the upper (oropharynx) and main (trachea and bronchi) respiratory tract⁷⁸ (see Figs. 48.2 and 48.3).

Early prediction of which patients are vulnerable to resuscitation stresses, increased pulmonary complications, respiratory failure, and mortality is complex and frequently not possible. Many attempts to identify prognostic indicators for patients with smoke inhalation injuries have been made.^{79,80} It has been difficult to identify reliable indicators of progressive respiratory failure in patients with smoke inhalation injury. Most of these studies have involved small numbers of patients and assessed a small number of clinical features. Prognostic estimations will ultimately rely on a system that allows quantification of the severity of inhalation injury.⁴¹ Many observational studies have compared outcomes with various grading systems.^{61,78,81,82} These grading systems often combine bronchoscopic findings with a small number of other clinical findings. However, it has been recognized that proximal injury observed by bronchoscopy is frequently greater than the peripheral, parenchymal injury. Masanes and colleagues⁸³ found that inhalation injury could be diagnosed by fiberoptic bronchoscopy in some burn patients who were otherwise asymptomatic. Liffner and colleagues⁸² found that their scoring system for grading the severity of bronchoscopic evidence of inhalation injury did not correlate with the development of acute respiratory distress syndrome (ARDS). Similarly, although it is generally recognized that inhalation injury increases fluid resuscitation needs in burn patients, Endorf and Gamelli found no correlation of severity of bronchoscopic findings with fluid resuscitation requirements.⁶¹ In a review article, Woodson concluded that a consensus may be facilitated when a clinical variable or constellation of variables is identified that is reliably related to the development of respiratory failure or other complications in patients who have inhaled smoke.⁴¹ A large multicenter study combining the experience of several institutions is more likely to identify such a correlation. However, consensus in diagnosis and quantification of inhalation injuries may await a theoretic advance with identification of a mediator or marker of cell injury or cell death that reliably and in some concentration-dependent way correlates with pulmonary or systemic complications of inhalation injury. A widely accepted grading system for inhalation injury severity

is presently not available. However, a randomized controlled multicenter trial to validate a standardized scoring system for inhalation injury that can be used to both quantify injury severity and predict mortality after inhalation injury is warranted.⁴¹

MECHANICAL VENTILATION

Since the advent of positive pressure ventilation, there has been an understanding that this therapeutic maneuver can paradoxically cause harm as well as save lives. Numerous studies have tried to identify optimal ventilatory strategies, positive end-expiratory pressure (PEEP) levels, and modes. An open lung strategy with low-tidal-volume ventilation has been shown to be associated with improved outcome and reduced duration of ventilation.⁸⁴ In keeping with the ARDSnet data, low tidal volumes are mandated to minimize ventilator-induced lung injury (VILI).⁸⁵ An open lung strategy is advised due to the decrement of surfactant in this population, but no study has shown an improved outcome with higher levels of PEEP. The frequent casts that occur post smoke inhalation result in areas of collapsed alongside open lung, and application of PEEP may result in tidal hyperinflation in areas of the lung, whereas there is an inability to aerate the collapsed area of lung. Hence, frequent airway toilet with mucolytics is essential to minimize VILI. Newer modalities such as electrical impedance tomography to assess breath-to-breath changes have demonstrated the rapid changes in ventilatory inhomogeneities seen post smoke inhalation.⁸⁶ A number of specific modalities have been suggested specific to the ventilatory idiosyncrasies associated with smoke inhalation.⁸⁷

An alternative to the classic ARDSnet low tidal volume ventilation in patients with ARDS may be high-frequency oscillation. A meta-analysis to determine the clinical and physiologic effects of high-frequency oscillation compared with conventional ventilation in patients with ARDS displayed improved survival and it is unlikely to cause harm. As ongoing large multicenter trials will not be completed for several years, these data help clinicians who currently use or are considering this technique for patients with ARDS.⁸⁷

The volumetric diffusive ventilator (VDR) is a pneumatically powered, pressure-limited ventilator that stacks oscillatory breaths to a selected peak airway pressure by means of a sliding venturi called a Phasitron, resulting in low tidal volumes. Exhalation is passive and a level of continuous positive airway pressure (CPAP) can be selected. In addition, VDR reestablishes the physiologic diffusive gas exchange, whereas standard ventilation modes induce a convective gas exchange.⁸⁸ A prospective clinical analysis revealed an improved gas exchange and a decrease in peak pressures.⁸⁹ A retrospective study in 330 patients with inhalation injury even reported a lower mortality rate.⁹⁰ Although these studies compared the VDR to high-volume ventilatory strategies, data regarding a comparison with modern low-tidal volume ventilation are still lacking. This may represent one reason why VDR is not universally accepted. Another factor might be that the VDR differs from other ventilators and, therefore, requires special training. In addition, tidal and minute volumes cannot be monitored, and humidified

air as well as nebulized saline are necessary to prevent airway desiccation.⁴⁷

As in conventional long-term ventilation of patients, common complications must be considered. Mosier and associates⁹¹ documented that patients with combined thermal and inhalation injury requiring urgent intubation or prolonged ventilation have a high incidence of bacterial bronchial contamination. Inhalation injury creates a damaged tracheobronchial mucosa, and early intubation provides a portal for bacterial contamination. In patients with smoke inhalation that necessitated urgent intubation, a 50% incidence of ventilator-associated pneumonia (VAP) has been described.⁹²

The use and timing of tracheostomy in burn patients elicit a great deal of passionate discussion but very little solid data. Burn survivors with TBSA >60% are more likely to undergo repeated surgery and have burns to the head and neck region, therefore increasing the requirement for tracheostomy. However, an association has been demonstrated between tracheostomy and high prevalence of chest infection in patients with inhalation injury, greater burn size, and prolonged mechanical ventilation.⁹³ The authors would advise caution in overinterpreting this study, as association does not infer causation, and sicker patients tend to be ventilated for longer periods, resulting in a higher incidence of both tracheostomy and VAP. The tracheostomy allows for less sedation, earlier mobilization, and a more comfortable method of ventilation for a long-term patient.

NEBULIZATION TREATMENTS

As described previously, smoke-inhalation injury causes a destruction of the ciliated epithelium that lines the tracheobronchial tree. Casts produced from these cells, polymorphonuclear leukocytes, and mucus can cause upper-airway obstruction, contributing to pulmonary failure.²¹ In the early 2000s, it was proposed that a combination of aerosolized heparin and a mucolytic agent, *N*-acetylcysteine, can ameliorate cast formation and reduce pulmonary failure secondary to smoke inhalation. In a study of 90 consecutive pediatric burn patients at the Shriners Burns Hospital at Galveston, Texas, who had bronchoscopically diagnosed inhalation injury requiring ventilatory support, 5000 units of heparin and 3 mL of a 20% solution of *N*-acetylcysteine aerosolized every 4 hours the first 7 days after the injury resulted in a significant decrease in reintubation rates, in incidence of atelectasis, and in mortality for patients treated with the regimen when compared with controls, and this practice has ever since been part of the ventilation protocol at this institution.⁹⁴

NONVENTILATORY PULMONARY TREATMENTS

Extracorporeal membrane oxygenation (ECMO) is used in specialized centers for neonatal, pediatric, and adult respiratory and cardiac failure. It requires a highly skilled team of intensivists and perfusionists, and echocardiographic support is essential for optimal usage of this modality.⁹⁵ The goal of ECMO is to support gas exchange, allowing the intensity of mechanical ventilation to be reduced and thus decreasing the potentially injurious effects of

ventilator-induced lung injury until recovery. Furthermore, ECMO may be considered the definitive rescue therapy for refractory life-threatening hypoxemia, as pulmonary gas exchange is not required. Our group performed a systematic review of the literature to collect all available clinical data in order to elucidate the role and present evidence of ECMO on severe hypoxemic respiratory failure resulting from burn and smoke inhalation injury.⁹⁶ Only a small number of clinical trials with a limited number of patients were available. The data suggested a higher ECMO therapy survival than nonsurvival rate of burn patients suffering acute hypoxemic respiratory failure. ECMO run times of less than 200 hours correlate with higher survival compared to 200 hours or more, and scald burns show a tendency of higher survival than flame burns. However, based on the low number of studies and patients, as well as the low grade of evidence of these studies, there are currently inadequate data to support the use of ECMO in burn or smoke inhalation injury. Even though the reports are promising, especially in the pediatric burn population, this review highlighted the lack of evidence for the use of ECMO in this setting. ECMO in adult respiratory failure is controversial, as early randomized trials showed poor outcomes⁹⁷⁻⁹⁹ and use has been limited to highly specialized centers. Nevertheless, ECMO technology and expertise have improved. More recently, the Conventional Ventilation or ECMO for Severe Adult Respiratory Failure trial¹⁰⁰ and selected case series have shown improved outcomes, with survival of 75% to 85% in refractory respiratory failure.^{101,102} Therefore, randomized controlled trials on patients with burn and smoke inhalation injury are warranted to provide definitive recommendations and to further advance this therapeutic option in patients where other ventilatory modalities have failed. Currently, there are large animal studies assessing the efficacy of ECMO in severe smoke inhalation, with promising results.¹⁰³

EXPERIMENTAL TREATMENTS

Against the background of the current literature, there has been a remarkable increase in our knowledge about the pathogenesis of smoke inhalation injury. There are several promising therapeutic approaches, including the nebulization of β_2 -agonists, antioxidants, or anticoagulants as well as the use of different ventilation modes.¹⁰⁴⁻¹¹² However, as has been highlighted, smoke inhalation may begin as a single organ injury, but rapidly becomes systemic. Hence, although treatment paradigms may focus on smoke inhalation, it is more frequently a mixed insult of smoke and burn, smoke and pneumonia, smoke and toxicology, and smoke and trauma. Even isolated smoke inhalation generally induces distant organ dysfunction rapidly post injury. Hence, it is unlikely that a single “magic bullet” will be found for this condition, and the clinician is best equipped with a comprehensive understanding of the complex pathophysiology and multitudinous clinical presentations of smoke inhalation injury. The treatment can then be patient and inhalation specific, with a systemic rather than organ-specific approach to these patients (see [Table 48.1](#)).

KEY POINTS

- Smoke inhalation represents a huge burden of disease in patients with and without burn injury.
- Early signs may be mild so a high index of suspicion must be maintained, particularly in burn victims from an enclosed environment.
- Prophylactic control of the airway should be considered in patients with worsening symptoms.
- Concomitant poisoning with carbon monoxide or cyanide should be considered where an enclosed smoke inhalation occurs, and definitive treatment should be considered early.
- Bronchoscopy is a more useful tool than chest radiograph to determine severity of inhalation injury.
- Injurious ventilatory parameters can exacerbate the acute and late phase lung injury.
- Despite a great deal of research, exemplary critical care management is the only process that improves outcome in smoke inhalation management.

SUMMARY

Immunologic lung disease can arise in any anatomic compartment of the lung. Examples include the airways in bronchiolitis obliterans, the parenchyma in idiopathic pulmonary fibrosis (IPF), and blood vessels in vasculitis. In each instance these illnesses may prove severe enough to merit intensive care unit (ICU) management for diagnosis and treatment. Immunologic lung diseases tend to share three features during critical illness. First, restrictive lung physiology is generally present, so the risk of lung overdistention and associated ventilator-induced lung injury is real. Second, pulmonary hypertension may complicate management of the circulation. Finally, infection due to immunocompromise and drug-induced lung injury must be considered throughout critical illness, because these infections represent common and potentially treatable precipitants of crisis. Early recognition and treatment of immunologic lung diseases and their complications are essential to avoid permanent lung damage or death.

The focus of this chapter is immunologic lung disease. The emphasis is on those disorders that are likely to present to the medical intensivist. Asthma and neuromuscular diseases are covered elsewhere in this book and are not reviewed here.

CLINICOPATHOLOGIC CONSIDERATIONS DURING MECHANICAL VENTILATION

The lungs of patients with immunologic diseases, in particular, interstitial lung diseases such as IPF and connective

tissue lung diseases, exhibit restrictive physiology with decreased lung volumes, decreased parenchymal compliance, and a loss of functional capillary beds leading to a reduction in the diffusing capacity.¹ In this manner the functionally smaller lungs (baby lungs) of these patients resemble the lungs of patients with the acute respiratory distress syndrome (ARDS). This concept is supported by computed tomography (CT) findings of heterogeneous disease involvement in the lungs of patients with both IPF and ARDS. This parallel can be used as a framework for managing tidal volumes during mechanical ventilation of patients with immunologic lung disease and respiratory failure. If large tidal volumes (or excessive inflation pressures) are used, relatively normal areas of lung will be overdistended, potentially exacerbating lung injury. Limiting tidal volumes to 6 mL/kg predicted body weight in patients with acute lung injury (ALI) or ARDS saves lives.² Similar data are not available regarding safe parameters for ventilating patients with chronic restrictive lung diseases, but limiting tidal volumes to roughly 6 mL/kg (and raising the rate accordingly) carries little risk. Moreover, retrospective analysis of mechanically ventilated patients without ALI/ARDS suggests that large tidal volumes may produce ALI (odds ratio 1.3 for each milliliter above 6 mL/kg predicted body weight).³ Because there is little evidence that intrinsic positive end-expiratory pressure (PEEP) plays a physiologically important role in respiratory failure in patients with interstitial lung disease, rapid ventilatory rates are tolerated.¹ This approach may allow ventilation without resorting to permissive hypercapnia, which may aggravate pulmonary hypertension.^{4,5} As in the ARDS lung, it seems likely that

nonfunctional, diseased lung units exist alongside those with essentially normal function. However, unlike the acutely injured lung, atelectatic lung units available for recruitment through the use of elevated end-expiratory pressure are rare in conditions such as IPF. There is probably little clinical advantage to using high PEEP in patients with restrictive lung diseases; in fact, high levels of PEEP may be detrimental by overdistending the lung, as well as by contributing to cor pulmonale, as described later. In a cohort of ventilated patients with interstitial lung disease, high PEEP during the first 24 hours of mechanical ventilation was one of the independent determinants of death.⁶ Although it is likely that high PEEP served as a marker (rather than a cause) of severity in this study, high PEEP should nevertheless be applied cautiously to minimize harm.

Another clinicopathologic process to consider in the ventilatory management of the patient with immunologic lung disease is pulmonary hypertension. Pulmonary artery pressures are chronically elevated in advanced stages with lung fibrosis, and this pressure increases further with the increased cardiac output that accompanies exercise, fever, and hypercarbia.^{5,7} Pulmonary hypertension may eventually lead to cor pulmonale because of increased right ventricular afterload.⁸ Mechanical ventilation may interact adversely with pulmonary hypertension. Positive-pressure ventilation alone impairs right-sided heart function, and this effect is exaggerated by PEEP.⁹ PEEP increases afterload by increasing pulmonary vascular resistance.¹⁰ The resulting increase in wall tension decreases right ventricular perfusion, which leads to myocardial ischemia.^{10,11} Right ventricular ischemia may cause further dysfunction and dilation of the right side of the heart, in addition to diastolic dysfunction of the left ventricle (through ventricular interdependence), producing a cycle of progressively deteriorating circulatory function.⁸ Thus, it is important to minimize further increases in pulmonary artery pressure and to maintain adequate systemic pressure to preserve perfusion of the right ventricle. Additionally, adequate oxygenation is essential to prevent reflex increases in pulmonary artery pressure and to maintain peripheral oxygen delivery. Finally, hypercapnia, which tends to raise pulmonary artery pressures, should generally be avoided. Because predicting the degree of pulmonary hypertension clinically is difficult—and the need to avoid increases in pulmonary artery pressures is so important—we advocate liberal use of echocardiography. Other forms of monitoring, such as central venous saturation measurement or pulmonary artery catheterization, might also be useful. When acute-on-chronic cor pulmonale compromises the circulation, dobutamine or norepinephrine is often helpful.¹² Inhaled nitric oxide or inhaled prostacyclin probably plays some role, at least to buy time in the critically impaired patient.^{13,14} The role of newer pulmonary vasodilators such as bosentan and sildenafil in patients with acute cor pulmonale is unclear.

Rescue therapies such as extracorporeal membrane oxygenation or pumpless extracorporeal lung assist devices may be of benefit in selected cases when used early.^{15,16} Data on noninvasive mechanical ventilation in immunologic lung disease is limited. Two small studies show that noninvasive ventilation can be used to avoid intubation and risk for ventilator-associated pneumonia with comparable or better short-term survival.^{17,18}

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis is a disorder of unknown cause characterized by inflammation of the lower respiratory tract that usually leads to irreversible scarring. Current and former smokers are at increased risk, and there may be an inherited susceptibility to develop this disease.¹⁹⁻²¹ IPF most commonly presents as an outpatient illness with the insidious onset of exertional dyspnea and cough. On examination of the lungs, coarse crackles are found and clubbing of the fingers is characteristic.²¹ Chest radiographs may show a spectrum of findings from peripheral reticular densities to end-stage honeycombed lung.²¹ Alveolar infiltrates are unusual unless the patient has a concurrent lung cancer, pneumonia, or heart disease. The lung CT findings most closely associated with a pathologic diagnosis of IPF are lower-lung honeycombing and upper-lung irregular lines.²² The histologic examination of IPF reveals *usual interstitial pneumonitis*, which is characterized by inflammation, fibroblastic foci, areas of fibrosis, and remodeling of the lung parenchyma. The pulmonary fibrosis appears to follow collapse of involved alveoli.

Death in patients with IPF is most often directly attributable to progression of the underlying disease, even when the disease is only of moderate severity.^{21,23} Nevertheless, the clinician should seek treatable complicating conditions before making the difficult decision to withhold mechanical ventilatory support. Other causes of respiratory failure in IPF include infection, congestive heart failure, bronchogenic carcinoma, pulmonary embolism, and pneumothorax. Left ventricular failure is often found in association with IPF. These patients often have many of the risk factors (e.g., smoking, hyperlipidemia) that are associated with the development of atherosclerosis. For this reason, left ventricular failure may result from ischemic heart disease. Two other factors that may contribute to left ventricular failure in these individuals are systemic arterial hypertension and right ventricular failure. Hypoxemia may exacerbate these effects. A search for potentially treatable left ventricular failure should be considered in the deteriorating IPF patient.

Patients with IPF have about a 14-fold excess risk of developing lung cancer.²⁴ These malignancies are difficult to detect on an already abnormal chest radiograph and often cause rapid deterioration in the IPF patient. Treatment options for malignancy are often limited by poor pulmonary reserve. However, the diagnosis of lung cancer may greatly alter therapeutic planning. Furthermore, relieving airway obstruction and postobstructive infection may significantly palliate dyspnea.

Pulmonary embolism can also cause rapid deterioration and respiratory failure in IPF patients. Ventilation/perfusion scans often reveal nonsegmental perfusion defects and inhomogeneous areas of poor ventilation as a result of the IPF alone, so the utility of these scans in diagnosing pulmonary emboli is limited.²⁵ Pulmonary angiography or helical CT scanning should be considered if it can be performed safely.²⁵ We recommend empiric long-term anticoagulation for individuals with advanced IPF and severe pulmonary hypertension who are suspected of having pulmonary embolism but for whom a diagnostic evaluation is not feasible.²⁶

Pulmonary infection is difficult to document in patients with end-stage IPF and is a frequent cause of rapid decline. Many end-stage patients who die of respiratory failure have an infection as the inciting event. Only subtle changes on the chest radiograph are present in most of these patients. CT scanning may show alveolar infiltrates. Strong consideration should be given to the use of antibiotics in all IPF patients who suffer an acute respiratory decline. Bronchoalveolar lavage (BAL) or protected brush specimens from the distal airway may identify specific bacterial pathogens. Often the organism is not identified, and broad-spectrum antibiotics are used. The end-stage fibrotic lung has grossly distorted airways and multiple cystic airspaces, so this empiric coverage should be designed to also cover anaerobic organisms. In our experience, long courses of antibiotics are frequently required to adequately treat respiratory infections in IPF. We use 10 to 14 days of intravenous antibiotics followed by a prolonged course of oral therapy (6 to 12 weeks) aimed at treating anaerobic organisms.

An important factor to consider in patients with advanced IPF who develop respiratory failure is that this disease is largely irreversible. Although many exciting new therapies are under investigation, current treatments are largely ineffective in reversing the decline in lung function.²⁷⁻²⁹ Most patients with IPF who are in respiratory failure do not respond to corticosteroid therapy.³⁰ Cytotoxic therapy, such as cyclophosphamide, azathioprine, or cyclosporine, has not been shown to alter survival.^{31,32} Mortality rate after ICU admission is high, raising the question of appropriateness of mechanical ventilation in most cases, with the exception of perioperative support or as a bridge to lung transplantation.^{31,33-35} In a review of nine studies examining 135 patients with IPF ventilated in the ICU, the aggregate hospital mortality rate was 87% and the mortality rate within 3 months after discharge was 94%.³⁶ If patients are young, have early disease, or may be diagnosed with interstitial lung disease other than IPF, an open lung biopsy should be considered to exclude alternative treatable diseases. Recently, lung transplantation has become a viable option for some patients with end-stage IPF. It is imperative that physicians caring for these patients familiarize themselves with the referral protocols and policies of their respective regional transplant centers.

HAMMAN-RICH SYNDROME

Hamman-Rich syndrome, more recently called *acute interstitial pneumonia* (AIP), is a rapidly progressive interstitial pneumonia of unknown cause first described by Hamman and Rich.³⁷ The mean age of patients is 50 to 60 years, with a broad range and perhaps an increased risk for men.^{37,38} The patients often describe a prodromal viral-like respiratory illness typically followed by subacute progressive dyspnea, fever, and nonproductive cough.

AIP usually evolves over 1 to 3 months, and in some instances, it appears within 1 to 2 weeks after the onset of symptoms. Signs of right-sided heart failure may exist, and diffuse or basilar crackles may be found on auscultation of the lung. Diffuse, bilateral interstitial infiltrates are characteristic on chest radiograph. The findings on CT scan include diffuse, patchy alveolar ground glass infiltrates and

pleural effusion in one third of the cases.³⁹ Honeycombing may be present in subacute cases. Laboratory studies may show a leukocytosis with neutrophilia. Hypoxemia may be profound. Pulmonary function tests in patients without respiratory failure show a restrictive defect, generally without evidence of airway obstruction.³⁸

For many years experts believed that this disease was simply a rapidly progressive form of IPF; now this disease is felt to be more related to ARDS. The pathologic features of AIP are characterized by diffuse, active fibrosis, with proliferating fibroblasts and minimal collagen. These findings appear acute and relatively uniform in age and resemble the organizing stage of diffuse alveolar damage as seen in ARDS.⁴⁰

The prognosis of acute interstitial pneumonitis is poor, with only about a 40% short-term survival rate. Although the short-term mortality rate is similar to that for acute exacerbation of IPF, AIP survivors have near complete recovery of lung function in contrast to those with IPF.^{41,42} Supportive care may involve ventilatory support. Antibiotics to treat possible underlying infection and corticosteroids to treat inflammation have been used in many cases, but the efficacy of these treatments is not proved.³⁸ In one small series, early efforts to exclude infection combined with lung-protective ventilation and high-dose corticosteroid therapy led to success in 8 of 10 patients.⁴³ We recommend rigorous exclusion of an infectious cause including open lung biopsy, if necessary, before considering any immunosuppressive therapy.

ALVEOLAR HEMORRHAGE SYNDROMES

Perhaps the most striking immunologically mediated lung diseases are those that present with alveolar hemorrhage. These disorders require prompt diagnosis and management. We limit our comments here to the disorders that most commonly present as alveolar hemorrhage: Goodpasture's syndrome, Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), catastrophic antiphospholipid syndrome (CAPS), systemic lupus erythematosus (SLE), and idiopathic pulmonary hemosiderosis. [Box 49.1](#) provides a more complete list of disorders that can lead to alveolar hemorrhage.

An essential goal of managing patients with alveolar hemorrhage is prompt diagnosis of the underlying disorder ([Fig. 49.1](#)). The first step is to document alveolar hemorrhage. The classic triad of hemoptysis, anemia, and diffuse infiltrates on chest radiograph strongly suggests alveolar hemorrhage, yet many patients with significant alveolar hemorrhage do not have hemoptysis.⁴⁴ Consequently, the absence of hemoptysis does not exclude the presence of alveolar hemorrhage. Thus, diffuse pulmonary infiltrates, respiratory distress, and anemia associated with clinical evidence of glomerulonephritis or other conditions associated with vasculitis should arouse suspicion for alveolar hemorrhage, even in the absence of hemoptysis.

Before any specific therapy is instituted, it is important to document the presence of alveolar hemorrhage. Other processes that result in diffuse alveolar filling must be excluded, such as inflammatory exudate from infection, cardiogenic pulmonary edema, and ARDS. In addition, one should

 Idiopathic pulmonary hemosiderosis

*Idiopathic alveolar hemorrhage with pauci-immune necrotizing or crescentic glomerulonephritis is classified as nonspecific systemic vasculitis (presumptive).

Adapted from Leatherman JW: Diffuse alveolar hemorrhage in immune and idiopathic disorders. In Lynch JP III, De Remee R (eds): *Immunologically Mediated Pulmonary Diseases*. Philadelphia, JB Lippincott, 1991.

exclude hemorrhage from airway sources such as cancer, bronchitis, bronchiectasis, or excessive anticoagulation or an endogenous coagulation defect. Perhaps the most valuable test for documenting alveolar hemorrhage is bronchoscopy with BAL. Blood-tinged lavage fluid or frank blood in the airways is usually present.⁴⁵ Another test that can be used involves staining alveolar macrophages retrieved by lavage for hemosiderin. Normal individuals will have few hemosiderin-laden macrophages in BAL, but the intensity of staining and percentage of cells staining positive have been found to be predictive of alveolar hemorrhage.^{46,47} We feel, however, that this test is of questionable clinical value. If patients have sufficient acute bleeding to cause infiltrates on chest radiograph, this should be seen easily in the lavage fluid. If the only evidence for hemorrhage is the presence of hemosiderin-laden macrophages, we would propose that the acute infiltrates are the result of another cause. Similarly, the negative predictive value of this test can be questioned because it may take up to 48 hours for intracellular hemosiderin accumulation after an acute bleed.⁴⁸ Documentation of an elevated diffusion capacity for carbon

monoxide (DLCO) is also a means of evaluating for alveolar hemorrhage but is not practical during active bleeding or critical illness.^{49,50} Bowley and coworkers demonstrated the usefulness of this measure as a sensitive index of recurrent alveolar hemorrhage in patients undergoing treatment.⁵⁰

Treatment consists of supportive care including mechanical ventilation, prevention of infections and organ damage and immunosuppressive therapy directed at the underlying process. Rescue therapies such as recombinant factor VIIa and extracorporeal membrane oxygenation have been reported to be successful in anecdotal cases of refractory alveolar hemorrhage.⁵¹⁻⁵⁵ Survival following alveolar hemorrhage due to immunologic lung disease tends to be better compared to patients with alveolar hemorrhage from thrombocytopenia or sepsis.⁵⁶

GOODPASTURE'S SYNDROME

Goodpasture's syndrome accounts for 20% to 30% of the cases of alveolar hemorrhage.⁵⁷ This disease is a classic pulmonary-renal syndrome with a high mortality rate from alveolar hemorrhage or renal failure if untreated. Anti-basement membrane antibody is a universal finding in this disease. Antibody deposition along the glomerular basement membrane (GBM) undoubtedly contributes to the renal pathologic examination of this disease; however, other cofactors, in addition to anti-GBM antibody, may be necessary for alveolar hemorrhage to develop. A higher incidence of alveolar hemorrhage has been reported in smokers with anti-GBM antibody disease.⁵⁸ Experimental studies also showed that exposure to 100% oxygen in animals with circulating anti-basement membrane antibody resulted in alveolar hemorrhage, whereas unexposed animals did not develop lung disease.⁵⁹ Genetic studies have shown a strong association with HLA-DRB alleles.^{60,61}

A 2:1 male-female ratio exists with a median age of 21 years in patients with Goodpasture's syndrome.^{62,63} Alveolar hemorrhage is the most common presentation of Goodpasture's syndrome. Evidence of renal involvement is usually present; however, some patients may only have microscopic hematuria.⁵⁷ Untreated, Goodpasture's syndrome carries a mortality rate approaching 100%, the cause of death being equally divided between uremia and alveolar hemorrhage.⁶³ With prompt dialysis, plasma exchange, and immunosuppression, however, the acute mortality rate of the disease is about 10%, with diffuse alveolar hemorrhage being the most common cause of early death.⁶⁴

The evaluation of patients suspected of having Goodpasture's syndrome should include confirmation of alveolar hemorrhage, evaluation for renal disease, and testing for anti-basement membrane antibody. Circulating anti-basement membrane antibody can be demonstrated in more than 95% of patients through radioimmunoassay or enzyme-linked immunosorbent assay (ELISA).⁶⁵ Kidney biopsy should also be considered to confirm the diagnosis and to document the extent of glomerular loss. The characteristic glomerular lesion shows strong linear deposition of immunoglobulin G (IgG) along glomerular capillaries.⁵⁷ Other histologic features include segmental, necrotizing, crescentic glomerulonephritis indistinguishable from that found in other forms of vasculitis. Walker and colleagues⁶⁶ demonstrated that patients with greater than 85% crescents

on biopsy were significantly less likely to regain renal function. Lung biopsy is rarely necessary and often nonspecific.

Treatment consists of dialysis, plasma exchange, and immunosuppressive therapy. Immunosuppression usually includes both cyclophosphamide and corticosteroids.⁶⁷ Dialysis should be performed early to reverse uremic platelet dysfunction and to prevent fluid overload because both factors may perpetuate alveolar hemorrhage. Mechanical ventilation may be necessary to provide respiratory support, as well as to facilitate clearing blood from the airways. When mechanical ventilatory support is used, efforts should be made to select lung-protective tidal volumes and to minimize the fraction of inspired oxygen. We also aggressively treat possible respiratory infection because it may precipitate and perpetuate alveolar hemorrhage. If the patient has received drugs that impair platelet function, such as aspirin, we also administer platelets in cases of life-threatening hemorrhage. Alveolar hemorrhage generally responds within 1 to 3 days to this treatment.⁶⁸ In refractory cases, there has been anecdotal response to

mycophenolate or to anti-CD20 antibody. Once the patient has recovered, the importance of maintenance immunosuppression in preventing recurrent alveolar hemorrhage cannot be overemphasized.^{57,68,69}

WEGENER'S GRANULOMATOSIS

Another form of vasculitis that commonly presents as alveolar hemorrhage is WG. This disorder is characterized by a granulomatous vasculitis involving the upper and lower airways and is associated with rapidly progressive renal failure. WG represented 15% of the cases of alveolar hemorrhage in a series reported by Leatherman.⁵⁷ The incidence of pulmonary hemorrhage in this disorder is reported to vary between 12% and 30%.^{70,71} Clinical findings that may suggest a diagnosis of WG include nodules visible on a chest radiograph and evidence of upper airway involvement including chronic otitis media, sinusitis, nasal septal perforation, and tracheal stenosis.⁷² Eye involvement with either proptosis or extraocular muscle entrapment may occur.⁷² Skin lesions may include petechiae, palpable purpura,

ulcers, vesicles, papules, and subcutaneous nodules.⁷⁰ Musculoskeletal findings include myalgias, arthralgias, and pauciarticular or migratory arthritis. Neurologic manifestations include sensorineural deafness, mononeuritis multiplex, and cranial nerve palsies.^{70,72} Subglottic tracheal stenosis or obstruction can occur in these patients and should be considered before endotracheal intubation is undertaken. In up to 10% of patients, tracheostomy may be required to manage the airway at some time during the course of their illness.⁷²

Laboratory findings in WG include leukocytosis, anemia, thrombocytosis, and an elevated erythrocyte sedimentation rate. A valuable laboratory test is the antineutrophil cytoplasmic antibody (ANCA), which detects IgG directed at a variety of neutrophil and monocyte antigens. Clinically important ANCAs are of two types: antiproteinase 3 antibodies (anti-PR3) and antimyeloperoxidase antibodies (anti-MPO). When serum containing these antibodies is applied to neutrophils and stained by indirect immunofluorescence, anti-PR3 produces a cytoplasmic pattern of staining (c-ANCA), whereas anti-MPO produces a perinuclear or nuclear pattern (p-ANCA). Both anti-PR3 (seen almost exclusively in WG) and anti-MPO (which may be seen in pauci-immune rapidly progressive glomerulonephritis, Churg-Strauss syndrome, and MPA) can be measured more directly by ELISA. The sensitivity of ANCA has been reported to be 80% to 96% in patients with active generalized (e.g., having renal involvement) WG, and generally these patients have both c-ANCA and anti-PR3 positivity. In the ANCA-associated systemic vasculitides, which include WG, alveolar hemorrhage has been found in patients who have tested positive for either c-ANCA or p-ANCA (see “Microscopic Polyangiitis” later). More recently, the presence of an immunoglobulin M (IgM) isotype of ANCA has been strongly associated with alveolar hemorrhage; conversely, patients lacking IgM ANCA may have a low risk for alveolar hemorrhage.⁷³ Frequently the diagnosis of WG relies on tissue examination. Biopsies of upper airway lesions are probably acceptable in nonemergent situations when diagnosis can be delayed. However, in the case of severe alveolar hemorrhage, there is frequently an emergent need for diagnosis so that effective treatment can be instituted. An open lung biopsy often provides the diagnosis. Potential infectious causes, especially mycobacterial and fungal pathogens, can also be excluded. Fauci and coworkers have developed a scheme of major and minor criteria for WG on the basis of histologic diagnosis. Three major pathologic manifestations were identified including parenchymal necrosis, vasculitis, and granulomatous inflammation⁷⁴; however, in 18% of biopsies, less distinctive histologic features were the predominant findings. If definitive tissue biopsy cannot be obtained, a WG with alveolar hemorrhage diagnosis should be based on the histologic finding of a small vessel vasculitis or crescentic glomerulonephritis, together with compelling clinical evidence of WG consisting of cavitary pulmonary nodules or characteristic upper airway involvement.⁵⁷ Moreover, the presence of a positive c-ANCA test can help to confirm the diagnosis.

The recommended treatment for alveolar hemorrhage resulting from WG includes high-dose corticosteroids and cyclophosphamide.^{57,75} We recommend that patients who

are critically ill receive intravenous methylprednisolone at doses up to 1 g daily for the first 3 days in addition to cyclophosphamide at 3 to 5 mg/kg for 3 to 5 days. After this period, the prednisone dosage is reduced to 1 mg/kg/day and cyclophosphamide is continued at 1.5 mg/kg/day. Most patients respond favorably to this regimen, but the mortality rate remains substantial, often because of renal failure or sepsis. Plasma exchange or intravenous immunoglobulin may be useful in patients with life-threatening diffuse alveolar hemorrhage or when disease persists despite corticosteroids and cyclophosphamide.⁷⁶ Other rescue therapies include rituxan,⁷⁷ trimethoprim-sulfamethoxazole, anti-tumor necrosis factor antibodies, and antilymphocyte antibodies. The supportive measures described earlier for alveolar hemorrhage in Goodpasture’s syndrome also apply to this disease.

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis is a systemic, small-vessel vasculitis. Symptoms may begin subtly with weeks to months of fever, weight loss, malaise, and myalgias. ICU admission is often precipitated by life-threatening diffuse alveolar hemorrhage, and MPA is probably the most common vasculitis to present this way. Renal failure caused by crescentic, rapidly progressive, focal segmental necrotizing glomerulonephritis can predate ICU admission or be recognized concurrently but eventually develops in nearly all cases without treatment. Joint and skin manifestations are occasionally seen, as well as peripheral nerve and gastrointestinal involvement. Most patients will have positive ANCA with specificity for MPO (p-ANCA), although some will be c-ANCA positive. Some patients initially suspected of having MPA will ultimately develop granulomatous upper airway disease, and the diagnosis is changed to WG.

Treatment requires high-dose corticosteroids and cyclophosphamide in the same doses as for WG. Intravenous immunoglobulin may be effective in difficult cases. Factor VIIa has also been tried, and the rescue therapies described earlier for WG may also be effective. For the patient with respiratory failure caused by alveolar hemorrhage, ventilator guidelines for ALI/ARDS should be followed. Once a patient survives the acute alveolar hemorrhage, there are reasonable prospects for long-term survival, although this depends to a large degree on whether renal function recovers. Pulmonary fibrosis is often present before, during, and after the initial diagnosis of MPA.⁷⁸

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

The term *antiphospholipid syndrome* was coined to describe patients with systemic thrombosis or recurrent fetal loss having increased antiphospholipid antibodies in the circulation. A subset presenting with widespread vascular thrombosis and a fulminating clinical course, often involving respiratory failure, was subsequently called the *catastrophic antiphospholipid syndrome* (CAPS).⁷⁹ This syndrome can occur in those without a recognized rheumatologic disease but also in those with SLE or other diseases.

CAPS generally has been considered a noninflammatory thrombotic disease leading to widespread ischemia and

necrosis, producing multiorgan failure and death. More recently, however, cases of alveolar hemorrhage have been described in the setting of antiphospholipid syndrome in which thrombosis was not evident clinically or pathologically. These authors proposed that a nonthrombotic mechanism for pulmonary capillaritis and alveolar hemorrhage should be sought.⁸⁰

Infections, trauma, procedures, drugs, and malignancy have been implicated as precipitating factors. Clinically there is often evidence of widespread arterial and venous occlusions. The renal, pulmonary, and central nervous systems are most often affected. Multiple pulmonary manifestations have been reported including pulmonary thromboembolism, pulmonary hypertension, and ALI in addition to diffuse alveolar hemorrhage. Serologic findings include elevated titers of anticardiolipin antibody or the lupus anticoagulant. Increased β_2 -glycoprotein I has been linked to CAPS.⁸¹

Treatment generally involves immunosuppression along the lines of treatment for other immune alveolar hemorrhage syndromes. Plasmapheresis may be effective.⁸² The role for anticoagulation in the acute setting of alveolar hemorrhage is uncertain, but we recommend first establishing control of bleeding with immunosuppressive therapy and plasmapheresis and then later instituting antithrombotic treatment.

SYSTEMIC LUPUS ERYTHEMATOSUS

In patients with SLE, a wide variety of lung lesions are found. Histologic evidence of alveolar hemorrhage can be found in 40% of patients at autopsy.⁸³ Massive alveolar hemorrhage is uncommon, being reported in only 5% of patients in one series of 99 patients with SLE and lung involvement.⁸⁴ Although massive alveolar hemorrhage may be the presenting manifestation of SLE, this is uncommon.^{85,86} The clinical presentation of alveolar hemorrhage in SLE is similar to that in other alveolar hemorrhage syndromes; however, fever as high as 39° C to 40° C may be a prominent feature.⁸⁴ At the time of alveolar hemorrhage, patients often manifest other typical clinical findings of SLE, particularly nephritis, highlighting the systemic nature of this disease.⁸⁷

The cause of alveolar hemorrhage in SLE is not entirely clear. In some patients, antiphospholipid antibodies, as discussed earlier, may play a role.⁸⁸ Pathologic studies of open lung biopsies have not always demonstrated immune complex deposition.^{83,86} Patients with SLE often show a microscopic angiitis on biopsy.^{85,87} Considerable clinical overlap between the alveolar hemorrhage syndrome and acute lupus pneumonitis exists.^{83,87} Because treatment of both lesions is similar, we recommend separating these two pulmonary manifestations on clinical grounds without the need for open lung biopsy, as long as infection has been adequately excluded.

Infection is the most important factor to exclude in diagnosing alveolar hemorrhage in the patient with SLE. At least half of the patients with SLE who present with infiltrates should be expected to have an infectious cause.⁸³ Because many of these patients are receiving immunosuppressive therapy and because SLE is associated with impaired cellular immunity, the differential diagnosis for infectious agents is broad and includes bacterial, fungal, mycobacterial, viral,

and parasitic pathogens. Bronchoscopy with lavage and transbronchial biopsies are the logical procedures used to search for an infectious cause. Open lung biopsy may be necessary in some cases.

Mortality rate from SLE-associated alveolar hemorrhage is variable in small series, ranging from about 20% to more than 85%.^{57,86,87} Many patients develop respiratory failure, and the need for mechanical ventilation is associated with an increased mortality risk.⁸⁷ This high risk for respiratory failure is multifactorial, with contributions from alveolar hemorrhage, a high prevalence of underlying atelectasis, and diaphragmatic weakness.^{89,90} We recommend treating these patients with both high-dose corticosteroids and cyclophosphamide in a regimen similar to that used for WG.

IDIOPATHIC PULMONARY HEMOSIDEROSIS

The diagnosis of idiopathic pulmonary hemosiderosis is, by definition, one of exclusion. The syndrome is typically an illness that presents in infancy or childhood.⁹¹ The disease is characterized by recurrent episodes of alveolar hemorrhage, although often these episodes may be subclinical.⁹² There have been familial clusters of cases.^{93,94} Some cases of unexplained alveolar hemorrhage with onset during adulthood have been reported. The specific treatment of this illness is not clear. Most patients do well during the acute episode with supportive care alone, but there may be a short-term benefit from corticosteroid therapy. Long-term corticosteroid treatment has been described in some cases.

CRYPTOGENIC ORGANIZING PNEUMONIA

Cryptogenic organizing pneumonia (COP), also termed *idiopathic bronchiolitis obliterans with organizing pneumonia* (BOOP), frequently presents as an acute illness with respiratory failure. This disease often responds well to therapy without residual respiratory deficit, if timely diagnosis and treatment are undertaken. COP presents throughout adult life and shows no particular demographic associations.⁹⁵ The presenting symptoms include cough, dyspnea, or both in more than two thirds of cases. Flulike symptoms are present in 14%, and patients usually present with subacute symptoms within 3 months.^{96,97} Examination of the lung reveals dry crackles in 50% to 75% of cases. Wheezing and finger clubbing are rarely seen. Up to 12% of patients can be expected to present with a normal physical examination.

The chest radiograph most often shows patchy alveolar infiltrates scattered throughout all lung fields. Interstitial infiltrates and nodular densities may be seen.⁹⁷ Some reports suggest that interstitial densities on chest radiograph may be associated with a worse prognosis.⁹⁸ High-resolution computed tomography (HRCT) of the chest shows predominantly subpleural or peribronchial areas of airspace consolidation, small nodules, or both in almost all cases.⁹⁹ These changes are not pathognomonic for COP, but the HRCT images may be useful for directing biopsies to abnormal areas. The results of physiologic testing characteristically reveal a restrictive ventilatory defect with reduced lung

volumes. Obstructive flow defects are seen only in smokers.⁹⁷ The DLCO is frequently abnormal, out of proportion to the other pulmonary function tests.⁹⁶ Resting and exercise-induced hypoxemia are almost always present.

BAL usually shows increased cellularity. An increased percentage of lymphocytes, neutrophils, or eosinophils may exist, but this finding does not help distinguish COP from other lung diseases.⁹⁷ The diagnosis is difficult to make from a transbronchial lung biopsy because the tissue samples obtained are often not large enough.⁹⁶ Transbronchial biopsy is, however, useful to rule out other disorders, especially infections. The gold standard for diagnosis is the open lung biopsy.⁹⁶ Findings include patchy areas of intraluminal polyps of granulation tissue and constrictive bronchiolitis, organizing inflammation within the alveolar ducts, interstitial mononuclear cell infiltrate of variable density, alveolar space foam cells, and the absence of honeycombing or extensive interstitial fibrosis.¹⁰⁰

COP may be associated with systemic diseases, certain inhalational exposures, or a drug reaction. A viral cause is hypothesized for at least a proportion of the cases of idiopathic COP.¹⁰¹ An association between COP and connective tissue diseases, especially rheumatoid arthritis (RA), exists.¹⁰² COP has also been reported in association with human immunodeficiency virus infection, radiation therapy, and smoking freebase cocaine.¹⁰³⁻¹⁰⁵ Thus, it appears that COP may appear secondary to a variety of pulmonary insults and may represent an aberrant healing process in the distal airspace.

The mortality rate of COP is about 5%.⁹⁶ Typically, prednisone is used to treat this disease at a dose of 1 mg/kg/day. For the critically ill patient in the ICU, higher doses of parenteral corticosteroids can be used. Additional immunosuppression with cyclophosphamide is usually not required in COP and is associated with a high rate of complications.^{106,107} When respiratory failure develops, the ventilatory management of COP is similar to that in patients with IPF, except that chronic pulmonary hypertension and right ventricular failure are less of a problem.

CONNECTIVE TISSUE DISEASES

Rheumatologic disorders affect the lungs in a variety of ways. Alveolar hemorrhage is discussed earlier. Interstitial fibrosis, vasculitis, pulmonary hypertension, and respiratory muscle weakness are mechanisms by which the patient with connective tissue disease may develop respiratory failure. In a recent study of 66 patients with connective tissue disease and respiratory failure, the most common underlying diagnoses were SLE, RA, and vasculitis.¹⁰⁸ Pneumonia was the leading cause of respiratory failure, followed by pulmonary edema and alveolar hemorrhage. The hospital mortality rate in this cohort was 62%. This section focuses on those rheumatologic disorders most likely to be encountered in an ICU.

LUPUS PNEUMONITIS

SLE is a systemic disorder characterized by widespread inflammation of serosal surfaces, skin, connective tissues, kidney, lung, and other organ systems. The characteristic

finding of SLE is the presence of circulating autoantibodies, particularly antinuclear antibodies, and immune complexes. Pleuropulmonary involvement is common.¹⁰⁹ For the purposes of this discussion, we define *lupus pneumonitis* as any acute presentation of respiratory disease and pulmonary infiltrates, associated with SLE, that is neither infection nor frank alveolar hemorrhage (see previous discussion). Matthay found acute presentation of lung disease in 11% of patients hospitalized for SLE.¹¹⁰ In 50% of these patients, lupus pneumonitis was the presenting manifestation of SLE, which is distinctly unusual in SLE-associated alveolar hemorrhage.⁸⁷

The patients typically have dyspnea, cough, and pleuritic chest pain. Fever and tachypnea are also frequently present. The chest radiograph characteristically shows bilateral basilar or diffuse infiltrates, but unilateral infiltrates may be present and atelectasis may be a prominent feature. An accompanying pleural effusion is often present.¹⁰⁹⁻¹¹¹ Cyanosis and basilar rales are often found on physical examination. The arterial blood gas frequently shows severe hypoxemia. Histopathologic findings on open lung biopsy are variable and may include areas of desquamative or unusual interstitial pneumonia, COP, and microscopic alveolar hemorrhage. Pulmonary infarction is associated with anticardiolipin antibody, and focal atelectasis from respiratory muscle weakness can be seen.¹¹¹⁻¹¹³ The rapidity of clinical deterioration can be alarming. The mortality rate for patients who present with the characteristic clinical features of lupus pneumonitis can be up to 50% despite treatment.^{110,113} The treatment of these patients usually includes high-dose corticosteroids. Cyclophosphamide and azathioprine have been used in cases of progressive disease.¹¹¹⁻¹¹³ In patients with acute, severe neurologic lupus, cyclophosphamide was more effective than high-dose corticosteroids.¹¹⁴ We recommend the initial use of both cyclophosphamide and high-dose corticosteroids in a regimen similar to that used to treat vasculitis (see previous discussion). Before initiating immunosuppressive therapy, it is essential to exclude infection with bronchoscopy or open lung biopsy. Maintaining a high suspicion for infection in the patient who is unresponsive to immunosuppression or who shows clinical deterioration despite treatment is also important.

RHEUMATOID ARTHRITIS

RA is a disease of subacute and chronic inflammation characterized by erosive arthritis that is usually symmetrical, affecting mainly the peripheral joints. A positive rheumatoid factor is present in at least 75% of cases. RA, like SLE, has a variety of associated pleuropulmonary manifestations that can present during the course of illness.¹⁰⁹ It is important for the intensivist to recognize the spectrum of lung disease associated with RA because many of the findings on chest radiograph can be ascribed to relatively benign disease.¹¹⁵ Moreover, even moderately severe chronic pulmonary disease may go undetected because it is obscured by musculoskeletal limitations. Two of the more common forms of rheumatoid involvement that present with severe lung disease are interstitial fibrosis and COP.

Interstitial fibrosis is a relatively common finding in patients who have RA. In the overwhelming majority of patients, this is an incidental finding and is asymptomatic.¹¹⁶

The clinical course of RA-associated interstitial lung disease is typically much more benign than that seen in IPF; however, a subset of patients presents with fulminant interstitial lung disease associated with RA.¹¹⁷ Like IPF, the physical examination frequently shows Velcro-like rales, and the chest radiograph in the more severe cases typically shows diffuse bilateral reticular or reticulonodular infiltrates.¹¹⁷

Patients with RA are generally admitted to the ICU with sepsis rather than complications of the arthritis itself.¹¹⁸ Most of these patients have been treated previously with corticosteroids or other immunosuppressive regimens. Airway management may be particularly challenging because many RA patients have limited mouth opening, atlantoaxial instability, or cricoarytenoid arthritis. Fiberoptic intubation is a necessary skill for safely managing patients with RA and ventilatory failure.

RA is the most common connective tissue disease to present with COP. This illness typically presents with a subacute onset of dyspnea. The presentation and pathologic features of COP associated with RA are indistinguishable from those of idiopathic COP.¹¹⁹ Diagnosis usually requires an open lung biopsy to define the histologic features. In a few patients the diagnosis is made by transbronchial biopsy. Bronchoscopy should be undertaken before immunosuppressive therapy to rule out infection. Treatment of this disorder is identical to the treatment of COP, but the prognosis for RA-associated COP appears to be worse.¹²⁰ For this reason, we consider cyclophosphamide earlier to treat this disease when it does not respond rapidly to corticosteroids.

PROGRESSIVE SYSTEMIC SCLEROSIS

Progressive systemic sclerosis (PSS) and the related disorder, the CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasis) syndrome, are disorders characterized by fibrosing inflammation of the skin with variable visceral involvement. Patients with PSS and CREST develop interstitial lung disease that histopathologically resembles the lung fibrosis associated with RA and IPF.¹²¹ The prevalence of pulmonary fibrosis detected by chest radiograph is approximately 36% in PSS and 20% in CREST.¹²² The clinical presentation is indistinguishable from other secondary causes of pulmonary fibrosis. Many of these patients also have chronic aspiration resulting from esophageal dysfunction, which can precipitate and exacerbate pulmonary inflammation and fibrosis.¹²³

The diagnosis of lung disease in PSS and CREST usually does not require an open lung biopsy. Pulmonary function tests characteristically reveal a restrictive ventilatory defect with low lung volumes.¹²⁴ The detection of circulating autoantibodies may be helpful in diagnosing these diseases.¹⁰⁹ Anticentromere antibody presence is associated with a lower incidence of pulmonary fibrosis in CREST.^{125,126} Anti-SCL-70 antibody presence is associated with a higher incidence of pulmonary fibrosis.¹²⁷ Bronchoscopy can be used to evaluate for an infectious process and to look for vegetable matter or lipid-laden macrophages, which may suggest chronic aspiration. Treatment of interstitial lung disease associated with PSS or CREST with cyclophosphamide has been shown to be effective in the National Institutes of Health Scleroderma Lung Study by improving

physiology, relieving dyspnea, and enhancing quality of life. Nevertheless, the prognosis remains poor. The role of steroids is unproved.

Pulmonary hypertension is another common manifestation of lung involvement in PSS and the CREST syndrome. This can occur without evidence of other lung disease, but it is often associated with interstitial disease. When accompanying interstitial lung disease, pulmonary hypertension is often more prominent than one would expect from the degree of interstitial lung disease alone. The prevalence of pulmonary hypertension in PSS has been found to be about 33%. In CREST the prevalence of pulmonary hypertension is at least as high.¹²⁸ The cause of pulmonary hypertension in these disorders is not well understood. Some experts have speculated that early in the course of disease there is a period of vascular reactivity associated with Raynaud's phenomenon.¹²⁹ This period is hypothesized to be followed by a period of increased pulmonary pressures associated with local hypoxia.¹³⁰ Finally, there is vascular remodeling with intimal thickening and loss of capillary beds.¹³¹

The patient with pulmonary hypertension may present with exertional dyspnea or impending respiratory failure, but pulmonary hypertension may also be asymptomatic.¹²⁸ Physical findings include those features commonly associated with PSS or CREST. Findings suggestive of cor pulmonale may be present, including jugular venous distention with prominent "a" waves, loud or palpable S₂, left parasternal lift, and an S₄ gallop that increases with inspiration. Although approximately 88% specific, the physical examination is only about 63% sensitive to identifying definite pulmonary hypertension in PSS.¹²⁸ The single best marker of underlying pulmonary hypertension is a low DLCO. When the DLCO is below 40% to 55% of predicted normal values, pulmonary hypertension is likely to be present.^{128,132} The sensitivity of this finding, irrespective of the presence of interstitial lung disease, is about 87% with a specificity of 88%.^{128,132} The electrocardiogram may show right bundle branch block, right ventricular hypertrophy, or right atrial enlargement. Echocardiography is highly specific for pulmonary hypertension if a Doppler gradient analysis of tricuspid regurgitation suggests pulmonary hypertension.¹³³ The gold standard has been pulmonary artery catheterization with documentation of an elevated pulmonary artery pressure and a normal pulmonary capillary wedge pressure.

Early intervention with vasodilating agents may alter the course of pulmonary hypertension by preventing progression that is dependent on high pulmonary artery pressures or by ameliorating angiogenesis or fibrosis. Bosentan, the dual endothelin receptor inhibitor, has been found effective in clinical trials of subjects with pulmonary hypertension including those with scleroderma.¹³⁴ Other treatments such as prostanoids, endothelin receptor blockers, and sildenafil may play a role in chronic management of the patient with pulmonary hypertension. In the acute ICU setting, treatment of acute-on-chronic cor pulmonale generally involves seeking treatable precipitants, infusing rapidly acting vasoactive drugs such as dobutamine, and giving short-acting pulmonary vasodilators such as inhaled nitric oxide or inhaled prostacyclin. In mechanically ventilated patients, tidal volumes should be limited to reduce the potential for superimposing ALI.

HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis, in the majority of cases, does not result in an illness that requires critical care management. The cases that do present acutely are important to identify because these patients respond well to treatment. Furthermore, identifying an inciting exposure can prevent serious relapse or progression to chronic lung disease. Acute and subacute hypersensitivity pneumonitis are the most likely forms of this illness to result in admission to the ICU. The cause of hypersensitivity pneumonitis involves exposure to an airborne agent (Table 49.1).¹³⁵ Associated symptoms include malaise, myalgia, fever, nonproductive cough, and dyspnea.¹³⁶ The patient's history may reveal an onset of symptoms within 4 to 6 hours of the exposure to a previously sensitized antigen.¹³⁷ The physical examination frequently reveals diffuse basilar lung crackles. The chest radiograph findings vary from normal to nodular or diffuse fluffy infiltrates. A predilection for involvement of the lung bases exists.¹³⁸ This is in contrast to the upper lung zone predominance seen in chronic hypersensitivity pneumonitis. The HRCT scan in the acute phase shows diffuse airspace consolidation that evolves to a fine nodular or reticulonodular pattern over the course of days to weeks. Laboratory studies generally show a leukocytosis with a leftward shift in neutrophils. Eosinophilia is variably present, usually at low levels.¹³⁶ A polyclonal gammopathy may be present. Specific serum precipitins should be interpreted only as evidence of exposure, not as definitive evidence of disease. Rheumatoid factor may be present in as high as 50% of cases.^{136,137} Pulmonary function tests usually show restrictive defects with maintenance of expiratory flow rates.¹³⁹

BAL nearly always shows increased cellularity.¹⁴⁰ In the acute phase of illness, within 24 to 48 hours of the onset of symptoms, BAL typically shows a predominance of neutrophils; as the illness progresses, BAL shows a predominance of lymphocytes, up to as high as 80%.¹⁴¹⁻¹⁴³ Most of the lymphocytes are suppressor/cytotoxic (CD8, suppressor cytotoxic; CD4, helper) T cells. The presence of many foamy macrophages in the BAL is also highly suggestive of hypersensitivity pneumonitis. Histopathologic examination of transbronchial biopsies or open lung biopsy shows an inflammatory process involving both the airspaces and the interstitium. A mononuclear cell infiltration with many lymphocytes exists. Foamy histiocytes and plasma cells can frequently be seen. Interstitial, often poorly formed, noncaseating granulomas may be present.^{135,139}

The differential diagnosis of acute hypersensitivity pneumonitis should include other causes of interstitial pneumonitis such as COP or AIP (Hamman-Rich syndrome). Organic dust toxic syndrome also occurs under similar environmental exposures as hypersensitivity pneumonitis but represents an acute response to inhaled bacterial and fungal cell wall products.¹⁴⁴ This illness tends to be more acute, resolves spontaneously, and often appears in case clusters because the response is not a specific allergic hypersensitivity. Atypical community-acquired pneumonia should also be considered in the critically ill patient. BAL and transbronchial biopsies are helpful in evaluating for an infectious cause. After the diagnosis of hypersensitivity pneumonitis is

Table 49.1 Hypersensitivity Pneumonitis (HSP) (Extrinsic Allergic Alveolitis): Reported Associations

Disease	Source of Particles
Farmer's lung	"Moldy" hay, grain, silage
Bird fancier's, breeder's, or handler's lung	Avian droppings or feathers
Humidifier or air conditioner lung	Contaminated water in humidification and air conditioning systems
Chemical worker's lung	Polyurethane foam, varnishes, lacquer
Bagassosis	"Moldy" bagasse (sugar cane)
Malt worker's lung	Moldy barley
Mushroom worker's lung	Mushroom compost
Sequoiosis	Redwood sawdust
Maple bark disease	Maple bark
Woodworker's lung	Oak, cedar, mahogany dusts; pine and spruce pulp
Cheese washer's lung	Moldy cheese
Suberosis	Cork dust
Sauna taker's lung	Contaminated sauna water
Pituitary snuff taker's lung	Heterologous pituitary snuff
Coffee worker's lung	Coffee beans
Miller's lung	Infested wheat flour
Fish meal worker's lung	Fish meal
Furrier's lung	Animal pelts
Lycoperdonosis	<i>Lycoperdon</i> puffballs
Compost lung	Compost
Wood trimmer's disease	Contaminated wood trimmings
Thatched roof disease	Dried grasses and leaves
<i>Streptomyces albus</i> HSP	Contaminated fertilizer
<i>Cephalosporium</i> HSP	Contaminated basement (sewage)
Detergent worker's disease	Detergent
Japanese summer house HSP	House dust?
Potato riddler's lung	Bird droppings
	"Moldy" hay around potatoes
Tobacco worker's disease	Mold on tobacco
Hot tub lung	Mold on ceiling
Winegrower's lung	Mold on grapes
Laboratory worker's HSP	Laboratory rat
Tapwater lung	Contaminated tapwater
Pauli's HSP	Laboratory reagent
Woodman's disease	Oak and maple trees

Adapted from Richerson HB, Bernstein IL, Fink JN, et al: Guidelines for the clinical evaluation of hypersensitivity pneumonitis. Report of the Subcommittee on Hypersensitivity Pneumonitis. *J Allergy Clin Immunol* 1989;84:839.

made, treatment usually includes corticosteroids and environmental counseling to avoid repeated exposure.

DRUG-INDUCED RESPIRATORY FAILURE

Drug-induced interstitial lung disease is a common complication of a variety of drugs including antibiotics and novel

molecular targeted agents. Pathologic examination can include interstitial pneumonitis (interferons, methotrexate), acute eosinophilic pneumonia (SSRIs, sulfamides), alveolar hemorrhage (abciximab, allopurinol, retinoic acid), BOOP (minocycline, nitrofurantoin), and diffuse alveolar damage (bleomycin, cyclophosphamide, gemcitabine). Diagnosis is challenging as there are no pathognomonic findings in lung biopsy. Bronchoscopy might be helpful when there is eosinophilic predominance in the lavage and a clinical correlation. We recommend empirically withholding the offending agent when a patient presents with any of abovementioned forms of lung disease unless a compelling alternative diagnosis such as an infection has been identified. This complication often resolves when the offending agent is discontinued, but steroids are commonly used in the ICU setting to hasten recovery. The pneumotox.com website is a comprehensive resource that has an ever-evolving list of drugs that have been implicated in lung disease.¹⁴⁵

SUMMARY

Patients with immunologic lung diseases can present with fulminant respiratory failure requiring care in an ICU. These conditions require a high index of suspicion because they may mimic many atypical pneumonia syndromes.¹⁴⁶ An efficient management strategy must include a rapid diagnosis; aggressive supportive care; and, often, therapy with immunosuppressive agents. Patients with an established diagnosis may already have received potent corticosteroids or cytotoxic therapy and are at great risk of opportunistic infection that can mimic a flare of their underlying immunologic lung disease.^{107,147} In addition, although in many cases immunomodulatory therapies have greatly altered the course of these diseases, treatment remains nonspecific and involves considerable toxicity. Indeed, in some series up to half of disease-related deaths can be attributed to treatment toxicity including infections and secondary malignancies.⁷⁰ Supportive management generally entails lung-protective ventilation and, in appropriate patients, surveillance for pulmonary hypertension.

KEY POINTS

- Immunologic lung disease may present with fulminant respiratory failure. Appropriate diagnosis requires a high index of suspicion combined with a thorough history and physical examination.
- Pulmonary infection may mimic, exacerbate, or result from the treatment of any immunologic lung disease. Lower airway sampling through BAL, parenchymal brushing, or biopsy may be required to exclude infectious causes.

KEY POINTS (Continued)

- Respiratory failure as a manifestation of end-stage IPF portends a grave prognosis. Looking for potentially treatable causes of impaired lung function such as infection, myocardial ischemia, heart failure, pulmonary embolic disease, and malignancy is important.
- When respiratory failure complicates IPF or fibrosis associated with connective tissue diseases, lung-protective ventilatory strategies should be used and the potential role of concurrent pulmonary hypertension should be considered.
- Bronchoscopy with lavage sampling of the distal airspace is a valuable tool in the documentation of alveolar hemorrhage and the exclusion of infection.
- Prompt institution of anti-inflammatory therapy after diagnosing COP or hypersensitivity pneumonitis may result in little or no long-term pulmonary dysfunction.

Vaccine-Preventable Diseases

Non-Vaccine-Preventable Diseases of Major Interest

GOALS FOR THE FUTURE

Intensive care units (ICUs) have contributed greatly to the survival of patients with trauma, shock states, and other life-threatening conditions¹⁻³ but are associated with a greatly increased risk of nosocomial (hospital-acquired) infection. Rates of nosocomial infection in patients requiring more than 1 week of advanced life support within an ICU are three to five times higher than in hospitalized patients who do not require ICU care.⁴⁻⁸ Infection, usually nosocomial, is the most common cause of death, directly or indirectly, of patients who survive the early period after major trauma or full-thickness burns and is the most commonly identified cause of multiple-organ dysfunction syndrome.⁹⁻¹¹

Although most of this book focuses on the diagnosis and management of critically ill patients in the ICU, nosocomial infections are clearly one of the most common and serious complications of ICU care and are usually

a consequence of invasive monitoring or life support therapies. Thus, they are greatly preventable, and it is appropriate that measures to prevent nosocomial infections be addressed.

Published guidelines for prevention are now available, based increasingly on randomized trials that have established the efficacy of specific control measures. Knowledge and technology of asepsis with regard to surgery and high-risk medical devices are now sufficiently advanced that, if applied consistently, the risk of nosocomial infection can be greatly reduced.¹²⁻¹⁵

INCIDENCE AND PROFILE

DEFINITIONS

Obtaining meaningful data on rates of nosocomial infection that can form the basis for comparisons within a hospital and, especially, among hospitals and that can also be used

 Additional online-only material indicated by icon.

to monitor secular trends and document the efficacy or lack of efficacy of control measures must begin with clear, unambiguous definitions. Although there are no standardized definitions for infection at specific sites that are universally accepted by clinicians or investigators, the Centers for Disease Control and Prevention (CDC) has published definitions for the purpose of surveillance of nosocomial infection within hospitals, which most U.S. centers and an increasing number of hospitals around the world have adopted (Box 50.1).^{16,17} For research purposes, more stringent definitions for specific infections will usually be necessary,¹⁸ especially for pneumonia.¹⁹

INCIDENCE

The incidence of hospital-acquired infection is most commonly expressed as the number of infections per 100 patients hospitalized and is highest in burn units^{7,20} and surgical ICUs,^{5-7,20-23} with intermediate risk in medical ICUs,^{*} and lowest risk in coronary care units.^{4,7,8,20}

Recognizing that the risk of nosocomial infection within ICUs is heavily influenced by the length of stay and that the length of stay ranges widely among ICUs in the same hospital and among different hospitals, the CDC has advocated the use of rates expressed per 1000 patient-days to permit more meaningful intrahospital and, especially, interhospital comparisons.²⁵⁻²⁷ Furthermore, recognizing the powerful influence of exposure to invasive devices on susceptibility to infection^{28,29} and the great variation in use of devices among different ICUs in the same hospital and among different hospitals, the CDC has further recommended surveillance of device-associated nosocomial infections expressed as infections per 1000 device-days.²⁵ Representative rates of device-associated nosocomial infection in U.S. hospitals, which can be used for intrahospital and interhospital comparisons, are shown in Table 50.1.²⁵⁻²⁷ In the future, device-associated infection rates will be sought in accreditation reviews by the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO)³⁰ as this influential organization continues to move toward measurement of patient outcomes as the most effective way to improve patient care in the United States.

PROFILE AND SECULAR TRENDS

Approximately 40% of endemic nosocomial infections within ICUs are catheter-related urinary tract infections, and 25% are pneumonias—most associated with endotracheal intubation and mechanical ventilatory support. Up to 10% of patients hospitalized in a medical-surgical ICU for more than 72 hours acquire a nosocomial bloodstream infection, most commonly from an intravascular device.^{25,31,32} Postoperative surgical site infections, *Clostridium difficile* infection, nosocomial sinusitis, and nosocomial meningitis account for the remainder.^{4,8,25,33-37}

Nearly 50% of nosocomial infections in the ICU are caused by aerobic gram-negative bacilli, especially *Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella pneumoniae*, and

Table 50.1 Rates of Device-Related Nosocomial Infection in U.S. Hospital Intensive Care Units (ICUs), Expressed per 1000 Device-Days

Type of Infection	Type of ICU	Rate (No. of Cases Per 1000 Device-Days)		
		2002-2004*	2006-2008†	2010‡
Catheter-associated urinary tract infection	Burn	6.7	7.4	4.7

	Medical	5.0	2.3	1.5
	Coronary	3.5	2.0	1.3

*Data from National Nosocomial Infections Surveillance System. National Nosocomial Infections Surveillance (NNIS) System Report, data summary from January 1992 through June 2004, issued October 2004. Am J Infect Control 2004;32:470-85.

†Data from Edwards JR, Peterson KD, Mu Y, et al. National Healthcare Safety Network (NHSN) report: data summary for 2006 through 2008, issued December 2009. Am J Infect Control 2009;37:783-805.

‡Data from Dudeck MA, Horan TC, Peterson KD, et al. National Healthcare Safety Network (NHSN) Report, data summary for 2010, device-associated module. Am J Infect Control 2011;39:798-816.

35% are caused by gram-positive cocci, most commonly coagulase-negative staphylococci, *Staphylococcus aureus*, and enterococci (Fig. 50.1).^{38,39} Almost 15% are caused by *Candida* species.^{38,39} Filamentous fungi such as *Aspergillus* and *Zygomycetes* are being increasingly encountered in patients with hematologic malignancy or those who received solid organ transplants.⁴⁰⁻⁴² *Legionella* species account for up to 10% of nosocomial pneumonias in centers that make efforts to diagnose *Legionella* infections.⁴³

The microbial profile of infections at individual sites in ICU patients is shown in Table 50.2.³⁹ There has been an unrelenting increase in nosocomial infections caused by intrinsically resistant organisms, especially *P. aeruginosa*, *Acinetobacter* species, and other resistant gram-negative bacilli; coagulase-negative staphylococci, *S. aureus*, enterococci; and *Candida*.^{31,38,39,44,45} Moreover, the incidence of infection caused by organisms with acquired resistance, especially methicillin-resistant *S. aureus* (MRSA); enterococci resistant to vancomycin (VRE), ampicillin, or both drugs; and gram-negative bacilli resistant to extended-spectrum β -lactams and fluoroquinolones, has increased even more sharply over the past several decades (Fig. 50.2).^{39,46} The recent emergence of carbapenem-resistant *K. pneumoniae*

*See references 4, 5, 7, 20, 23, 24.

Box 50.1 Definitions for Health Care–Associated Infection of the Centers for Disease Control and Prevention (CDC)

Primary Bloodstream Infection*

1. Patient has a recognized pathogen cultured from one or more blood cultures (does not include organisms considered common commensals—see below) AND the organism cultured from blood is not related to an infection at another site

OR

2. Patient has common commensal organisms (e.g., coagulase-negative staphylococci [including *S. epidermidis*], diphtheroids [*Corynebacterium* spp. not *C. diphtheriae*], *Bacillus* spp. [not *B. anthracis*], *Propionibacterium* spp., viridans group streptococci, *Aerococcus* spp., and *Micrococcus* spp.) cultured from two or more blood cultures drawn on separate occasions AND at least one of the following signs or symptoms: fever ($>38^{\circ}\text{C}$), chills, or hypotension AND signs and symptoms and positive laboratory results are not related to an infection at another site

Clinically Defined Pneumonia

1. For any patient, two or more serial chest radiographs with at least one of the following: new or progressive and persistent infiltrate, consolidation, or cavitation

AND at least one of the following:

- Fever ($>38^{\circ}\text{C}$ or $>100.4^{\circ}\text{F}$) with no other recognized cause
- Leukopenia (<4000 WBCs/ μL) or leukocytosis (12,000 WBCs/ μL)
- For adults >70 years of age, altered mental status with no other recognized cause

AND at least two of the following:

- New onset of purulent sputum or change in character of sputum, increased respiratory secretions, or increased suctioning requirements
- New onset of worsening cough, dyspnea, or tachypnea
- Rales or bronchial breath sounds
- Worsening gas exchange (e.g., O_2 desaturation [e.g., $\text{PaO}_2/\text{FiO}_2 \leq 240$]), increased oxygen requirements, or increased ventilation demands

Laboratory-Defined Pneumonia

1. Fulfillment of criteria listed above for clinically defined pneumonia,

AND at least one of the following:

- Positive growth in blood culture not related to another source of infection
- Positive growth in culture of pleural fluid
- Positive quantitative culture from minimally contaminated lower respiratory tract specimen (e.g., bronchoalveolar lavage $\geq 10^4$ CFUs/mL or protected specimen brushing $\geq 10^3$ CFUs/mL) (NOTE: an endotracheal aspirate is not a minimally contaminated specimen)
- $\geq 5\%$ bronchoalveolar lavage–obtained cells contain intracellular bacteria on direct microscopic examination (e.g., Gram stain)
- Histopathologic examination shows at least one of the following findings as evidence of pneumonia:
Abscess formation or foci of consolidation with intense neutrophil accumulation in bronchioles and alveoli
Positive quantitative culture of lung parenchyma
Evidence of lung parenchyma invasion by fungal hyphae or pseudohyphae

Symptomatic Urinary Tract Infection

Must meet at least one of the following three criteria:

1. Patient had an *indwelling urinary catheter in place* at the time of specimen collection or onset of signs or symptoms AND at least one of the following signs or symptoms with no other recognized cause:

- Fever ($>38^{\circ}\text{C}$)
- Suprapubic tenderness
- Costovertebral angle pain or tenderness

AND one of the following findings:

- A positive urine culture of $\geq 10^5$ CFUs/mL with no more than two species of microorganisms (cultures reported as “mixed flora” do not meet UTI criteria)
- A positive urine culture of $\geq 10^3$ and $<10^5$ CFUs/mL with no more than two species of microorganisms, AND at least one of the following findings: positive dipstick for leukocyte esterase or nitrite, pyuria (i.e., urine specimen with ≥ 10 WBCs/ μL of unspun urine or ≥ 3 WBCs/high-power field of spun urine), or microorganisms seen on Gram stain of unspun urine

OR

2. Patient had indwelling urinary catheter *removed within the 48 hours prior* to specimen collection or onset of signs or symptoms

AND at least one of the following signs or symptoms with no other recognized cause:

- Fever ($>38^{\circ}\text{C}$)
- Urgency, frequency, dysuria, or suprapubic tenderness
- Costovertebral angle pain or tenderness

AND one of the following findings:

- A positive urine culture of $\geq 10^5$ CFUs/mL with no more than two species of microorganisms (cultures reported as “mixed flora” do not meet UTI criteria)
- A positive urine culture of $\geq 10^3$ and $<10^5$ CFUs/mL with no more than two species of microorganisms, AND at least one of the following findings: positive result on dipstick testing for leukocyte esterase or nitrite, pyuria (see above), or microorganisms seen on Gram stain of unspun urine

OR

3. Patient did not have an indwelling urinary catheter in place at the time of, or within 48 hours prior to, specimen collection or onset of signs or symptoms

AND at least one of the following signs or symptoms with no other recognized cause:

- Fever ($>38^{\circ}\text{C}$) in a patient who is ≤ 65 years of age
- Urgency, frequency, dysuria, or suprapubic tenderness
- Costovertebral angle pain or tenderness

AND one of the following findings:

- A positive urine culture of $\geq 10^5$ CFUs/mL with no more than two species of microorganisms (cultures reported as “mixed flora” do not meet UTI criteria)
- A positive urine culture of $\geq 10^3$ and $<10^5$ CFUs/mL with no more than two species of microorganisms, AND at least one of the following findings: positive result on dipstick testing for leukocyte esterase or nitrite, pyuria (see above), or microorganisms seen on Gram stain of unspun urine

*All intravascular device-related bloodstream infections are classified with primary bloodstream infections.

CFUs, colony-forming units; FiO_2 , fraction of inspired oxygen; PaO_2 , arterial oxygen tension; UTI, urinary tract infection; WBCs, white blood cells.

Figure 50.1 Microbiology of nosocomial infection in the intensive care unit (ICU). Based on 13,317 infections occurring in ICU patients in 97 participating U.S. hospitals in the Centers for Disease Control's National Nosocomial Infections Surveillance System (NNIS), January 1992 through July 1997. (Data from Richards MJ, Edwards JR, Culver DH, Gaynes RP: Nosocomial infections in medical intensive care units in the United States. National Nosocomial Infections Surveillance System. Crit Care Med 1999;27:887-892.)

Table 50.2 Profile of Nosocomial Infections in the Intensive Care Unit (ICU)

Infection	Major Pathogen(s)	Risk Factors
Urinary tract infection	<i>Escherichia coli</i> <i>Pseudomonas aeruginosa</i> <i>Klebsiella pneumoniae</i> Other gram-negative bacilli <i>Enterococcus</i> spp.	Urinary catheter Monitoring of urine output Other urologic manipulation or bladder irrigations Renal transplantation Diabetes Female > male
Pneumonia	<i>Staphylococcus aureus</i> <i>P. aeruginosa</i> <i>Acinetobacter</i> spp. <i>Enterobacter</i> spp. <i>K. pneumoniae</i> Other gram-negative bacilli	Tracheostomy Endotracheal tube, reintubation Nasogastric tube Intracranial pressure monitoring Stress ulcer prophylaxis with histamine H ₂ blocker or antacids Immunosuppression Granulocytopenia Trauma, especially penetrating abdominal injury Gastrointestinal or radical gynecologic surgery
Surgical site infection	<i>S. aureus</i> Coagulase-negative staphylococci Enterococci <i>E. coli</i> and other gram-negative bacilli <i>Bacteroides fragilis</i> and other bowel anaerobes	Prolonged operation Immunosuppressive therapy Granulocytopenia Hepatic transplantation
Intravascular device-related bacteremia	<i>Candida</i> spp. Coagulase-negative staphylococci <i>S. aureus</i> <i>Enterococcus</i> spp. Gram-negative bacilli	Central venous catheter in place >5 days Heavy colonization of insertion site skin Femoral vein insertions Catheter guidewire exchanges
Contaminated infusate	<i>Enterobacter</i> spp. <i>S. marcescens</i> <i>Citrobacter</i> spp. <i>P. cepacia</i> or <i>Xanthomonas maltophilia</i>	
Antibiotic-associated diarrhea or colitis	<i>Clostridium difficile</i>	Prolonged antibiotic therapy, especially with clindamycin or broad-spectrum β -lactams Enteral tube feeding
Candidemia	<i>Candida</i> spp.	Broad-spectrum, prolonged antimicrobial therapy Mucosal or urinary colonization Central venous catheter Hyperalimentation Renal failure

Figure 50.2 Temporal trends in the proportion of isolates resistant to antibiotics among pathogenically important bacteria in U.S. intensive care units (ICUs), National Nosocomial Infections Surveillance System (NNIS) 1989–2004. FQRPA, *Pseudomonas aeruginosa* resistant to fluoroquinolones; MRSA, methicillin-resistant *Staphylococcus aureus*; 3CRKP, *Klebsiella pneumoniae* resistant to third-generation cephalosporins; VRE, vancomycin-resistant enterococcus. (From Centers for Disease Control and Prevention: Trends in antibiotic resistance in National Nosocomial Infections Surveillance (NNIS) system hospitals, 1989–2004. Available at http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RESTrend1995-2004.pdf. Accessed January 15, 2007.)

has become a significant problem as there are limited therapeutic options to treat this pathogen.^{39,47}

Nosocomial infections acquired in the ICU clearly differ from infections acquired in non-ICU patient care units within the same institutions. Overall rates are two to three times higher, and rates of ventilator-associated pneumonia (VAP) and primary bacteremia—most of which originate from intravascular devices—are 10 times higher. A far greater proportion of ICU-acquired infections are caused by antibiotic-resistant bacteria because the intensive antimicrobial therapy characteristic of modern-day ICUs grossly distorts patients' microflora. Moreover, more than half of all nosocomial epidemics now occur among the 10% of hospitalized patients confined to an ICU.^{20,31} Finally, the risk of occupationally acquired infection among health care workers (HCWs), particularly by bloodborne viruses and herpes simplex virus (HSV), is highest among ICU personnel, as contrasted with those who work in non-ICU patient care units (see *Protection of Health Care Workers in the Intensive Care Unit* later).

MORBIDITY AND ECONOMIC IMPACT

Nosocomial infections have a considerable impact on morbidity and mortality rates and are estimated to affect more than 2 million patients in U.S. hospitals annually.⁴⁸ Table 50.3 summarizes major studies that have examined mortality, length of stay, and costs associated with the major nosocomial infections in U.S. hospitals.²⁻¹⁹ Nosocomial infections have been ascribed by the National Institute of Medicine to be responsible for more than 80,000 hospital deaths each year and in 1995 resulted in more than \$5 billion in excess health care costs.⁴⁸ Considering that nosocomial infections

acquired by ICU patients account for nearly half of all infections in most hospitals, progress in reducing the incidence of infection acquired within ICUs could produce substantial economic benefits.

GENERAL INFECTION CONTROL MEASURES

HOSPITAL INFECTION CONTROL PROGRAMS

Beginning in the late 1960s, scattered U.S. hospitals began to establish infection control programs to conduct surveillance, to develop infection control policies, and especially to try to implement control measures more consistently.¹¹⁶ In 1976 JCAHO added to its requirements for hospital accreditation the establishment of a formal infection control program.

In the early 1970s the CDC undertook determining the effectiveness of nosocomial infection surveillance and control programs in the United States through the auspices of the Study of the Efficacy of Nosocomial Infection Control (SENIC). The goals of SENIC were to determine the extent to which infection control programs had been adopted by U.S. hospitals and to ascertain how much these programs had reduced rates of nosocomial infection. SENIC was launched by a survey of all U.S. hospitals to determine the characteristics of infection control programs and was completed in 1975–1976 by a review of more than 339,000 patient medical records in 338 randomly selected hospitals.¹¹⁷

The SENIC found that hospitals reduced their nosocomial infection rates by approximately 32% if their surveillance and infection control program included four components: (1) emphasis on both surveillance and an infection control program, (2) at least one full-time infection control practitioner for every 250 beds, (3) a trained hospital epidemiologist, and (4) surveillance of surgical wound infections with feedback of wound infection rates to practicing surgeons.¹¹⁸ However, the relative importance of each component varied for the four major types of nosocomial infections (surgical wound infections, urinary tract infections, bloodstream infections, and pneumonia).^{118,119} SENIC suggests that nearly one third of all nosocomial infections are in theory preventable, whereas a 1983 survey of surveillance and control programs in a random sample of U.S. hospitals found that failure to implement all essentials of the program, particularly to have an adequate number of infection control practitioners or a trained hospital epidemiologist or to disseminate wound infection rates to surgeons, was greatly limiting the potential for prevention: U.S. hospitals were estimated to be preventing only 9% of all infections.¹²⁰

It is hoped that surveillance and control programs will continue to evolve. Prevention of nosocomial infections is a major priority of the U.S. Public Health Service,¹²¹ JCAHO,³⁰ and the Institute of Medicine.¹²² With the shift to prospective-payment reimbursement, hospitals now have a powerful financial incentive to reduce their rates of nosocomial infection,¹²³ and it can be anticipated that efforts to prevent hospital-acquired infections will assume ever greater importance.

PATHOGENESIS AND EPIDEMIOLOGY

PATHOGENESIS

The occurrence of nosocomial infection reflects the conjunction in space and time of a pathogenic microbe and a vulnerable patient, catalyzed by events associated with hospitalization and the patient's care. Many patients admitted to an ICU are intrinsically more susceptible to infection because of underlying diseases or conditions associated with impaired immunity such as cancer, trauma,⁴⁹ or advanced age⁵⁰ or because of immunosuppression associated with malnutrition⁵¹ or therapy with corticosteroids,⁵² cancer chemotherapeutic agents,⁵³ or other immunosuppressive drugs.⁵⁴ Moreover, many drugs have indirect effects that increase susceptibility to infection, such as narcotics or sedatives that impair the capacity to protect the airway, or antacids or H₂-histamine receptor antagonists that neutralize gastric acidity, producing gastric overgrowth by gram-negative bacilli,⁵⁵ increasing the risk of nosocomial pneumonia.⁵⁶ Even transfusion therapy produces immunosuppression and increases the risk of nosocomial infection.⁵⁷

Moreover, most nosocomial pathogens exhibit resistance to antibiotics (see Figs. 50.1 and 50.2),^{44,45,47,58-61} and many are also more virulent because of (1) their capacity to subsist or even multiply in aqueous reservoirs for prolonged periods (e.g., pseudomonads⁶² or *Legionella pneumophila*⁶³); (2) the elaboration of endotoxins (e.g., all of the gram-negative bacilli) or exotoxins (*P. aeruginosa*,⁶⁴ *C. difficile*,⁶⁵ or *S. aureus*⁶⁶); or (3) the production of adhesions⁶⁷ or exoglycocalyx⁶⁸ (e.g., coagulase-negative staphylococci), conferring the capacity to adhere avidly and form biofilms on biologic and prosthetic surfaces resistant to host defenses⁶⁹ and even antibiotics.⁷⁰ Because most patients in ICUs receive broad-spectrum antibiotics, resistant nosocomial organisms have an enormous ecologic advantage and, in darwinian fashion, predictably supplant the normal cutaneous, respiratory, and gastrointestinal flora.

In most cases, colonization is the first step in the progression to nosocomial infection,⁷¹ especially if the patient is already vulnerable because of underlying disease, if the organism is more virulent or resistant to antibiotics, or if the patient has invasive medical devices that assist invasion by colonizing organisms, bypassing or further impairing host defenses.

RESERVOIRS AND TRANSMISSION

The epidemiology of an infection consists of the reservoirs and mode or modes of transmission of the pathogen or pathogens and those factors associated with an increased (or decreased) risk of infection. Understanding the epidemiology of an infection is essential to developing effective strategies for its prevention.

In the ICU the major reservoir of nosocomial organisms is the infected or colonized patient (Fig. 50.E1).²⁸ Whereas *Streptococcus pneumoniae*,⁷² *Mycobacterium tuberculosis*,⁷³⁻⁷⁵ *Legionella*,⁴³ *Aspergillus* and *Zygomycetes*,⁴⁰⁻⁴² measles,⁷⁶ rubella,⁷⁷ and influenza A⁷⁸ are transmitted by the airborne route, the best evidence suggests that most aerobic bacteria—particularly *S. aureus*,⁷⁹ enterococci,²⁹ and the enteric

gram-negative bacilli⁸⁰; many viruses such as hepatitis A, RSV,⁸¹ and rotaviruses⁸²; *C. difficile*⁸³; and even *Candida*⁸⁴—are spread in the ICU on the hands of medical personnel, who themselves are not infected or even permanently colonized. Surgery and exposure to invasive devices of all types greatly amplify transmission, colonization, and susceptibility to infection.^{28,85}

Outbreaks of *S. aureus*⁸⁶ or group A streptococcal infection⁸⁷ usually indicate a health care provider who is a carrier of the epidemic strain. Airborne spread of gram-negative bacilli is probably rare unless unusual environmental circumstances generate massively contaminated aerosols.⁸⁸

Increasing evidence suggests that many nosocomial infections acquired in the ICU derive from resistant organisms of enteric origin⁸⁹⁻⁹² or that are present on skin^{89,90} or in the lower respiratory tract⁹¹ on admission to the ICU. This explains the failure of conventional infection control practices, based on the use of barriers, to prevent extrinsically acquired infection.⁹³ Whereas food⁹⁴ and even enteral feeding preparations⁹⁵ are often heavily contaminated by microorganisms, studies have not conclusively linked such contamination to disease.

Nosocomial organisms originating from colonized or infected patients are readily perpetuated and spread in contaminated medical apparatus or devices²⁸ such as urine-collection receptacles,⁹⁶ respiratory therapy equipment,^{97,98} transducers used for hemodynamic monitoring,⁹⁹ dialysis machines,^{100,101} and fiberoptic bronchoscopes and endoscopes.^{98,102-104} Given the implicit close proximity of vulnerable ICU patients and the HCWs who have repeated contact with them each day, it is almost predictable that the ICU is a milieu within the hospital uniquely conducive to the epidemic infection, especially infections caused by antibiotic-resistant pathogens.

Although successful immune enhancement could in theory create a protective final barrier against infection by nosocomial organisms, the unique features of nosocomial infection—enormous microbial heterogeneity, pervasive effects of invasive devices and procedures, and often large infecting inocula—can overwhelm the healthiest patient's immune defenses. Measures to eradicate reservoirs of nosocomial pathogens and to block transmission, based on a thorough understanding of epidemiology, seem much more likely to be protective at present.

RISK FACTORS

Risk factor analysis using statistical techniques such as multivariate analysis can identify variables that put a patient at increased risk for nosocomial infection and further guide the development of preventive strategies. Risk factors based on prospectively collected data and, in most cases, the use of multivariate analysis are listed in Table 50.2 for urinary tract infection,^{105,106} pneumonia,^{107,108} surgical site infection,¹⁰⁹ intravascular device-related bloodstream infection,¹¹⁰ ventriculostomy-associated meningitis,¹¹¹ *C. difficile* infection,^{33,112} and candidemia.¹¹³⁻¹¹⁵

Critical care medicine is synonymous with cutting-edge, high-tech medicine; mechanical ventilatory support; hemodynamic monitoring; total parenteral nutrition; hemodialysis; intracranial pressure monitoring; innovative forms of

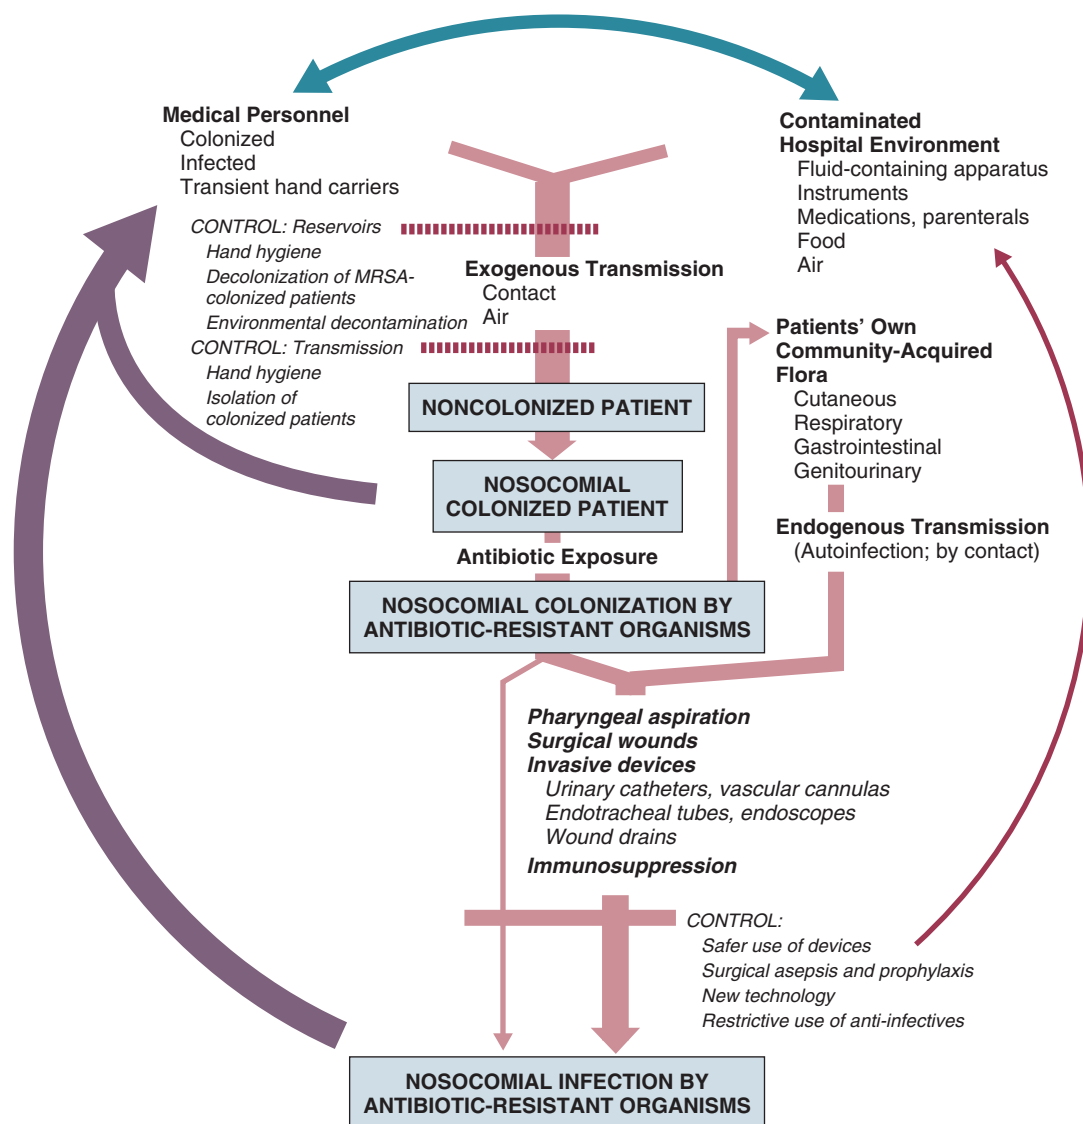

Figure 50.E1 The epidemiology of nosocomial infection. Transmission occurs mainly by contact spread and, to a much lesser extent, the airborne route. Aspiration, surgical wounds, and exposure to invasive medical devices enormously amplify transmission, colonization, and susceptibility to infection. (From Maki DG: Control of colonization and transmission of pathogenic bacteria in the hospital. *Ann Intern Med* 1978;89[Suppl]:777-780.)

Table 50.E1 Significant Risk Factors for Nosocomial Infection in Medical and Surgical Intensive Care Units (ICUs) as Determined by Multivariate Analysis of Prospectively Collected Databases

Risk Factor	Approximate Magnitude of Increased Risk*
Urinary catheter >10 days	3.2
ICU confinement >3 days	2.5
Intracranial pressure monitor	2.5
Arterial line	1.5
Shock	2.5

*Relative risk or odds ratio: values >1 denote significantly increased risk of infection, and ratios <1, decreased risk, vis-à-vis a protective effect.

From Craven DE, Kunches LM, Lichtenberg DA, et al: Nosocomial infection and fatality in medical and surgical intensive care unit patients. *Arch Intern Med* 1988;148:1161-1168.

surgery; and a huge arsenal of drugs, especially anti-infectives of every genre. This technology, more than anything else, has forced critical care medicine to accept the necessity for nosocomial infection control. In general, invasive devices of all types are far more important in determining susceptibility to nosocomial infection than underlying diseases (see [Tables 50.2](#) and [50.E1](#)). However, this should be viewed as welcome news: There is far more hope for reducing nosocomial infections in the coming years by innovative improvements in aseptic technique and advances in the technology of invasive devices than by breakthroughs that will reverse the ravages of chronic organ failure or degenerative diseases such as type 1 diabetes mellitus.

Table 50.3 Estimated Extra Days, Extra Charges, and Deaths Associated with Nosocomial Infections in U.S. Hospitals as Reported in Major Studies

Infection	Description	Average Extra Days in Hospital or ICU per Infection	Average Extra Charges or Costs per Infection (\$)	Excess Mortality	
				Unadjusted	Attributable
Surgical Site Infection					
Kirkland et al, 1999 ⁶¹⁰	CABG, vascular surgery, abdominal surgery, orthopedic surgery	6.5	3,089	NR	4.3%
Whitehouse et al, 2002 ⁶¹¹	Orthopedic surgery	14	17,708	NR	0.0%
Hollenbeak et al, 2000 ⁶¹²	Deep chest infection after CABG	20	20,012	NR	19.4%
McGarry et al, 2004 ⁶¹³	All major surgical procedures; only <i>Staphylococcus aureus</i> infections included	13	53,625	NR	16.8%
Herwaldt et al, 2006 ⁶¹⁴	All major surgical procedures	NR	3,021	1.2%	0%
Ventilator-Associated Pneumonia					
Fagon et al, 1993 ⁶¹⁵	Medical and surgical patients	13	NR	NR	27.1%
Heyland et al, 1999 ⁶¹⁶	Medical and surgical patients	4.3	NR	NR	5.8%
Bercault et al, 2001 ⁶¹⁷	Medical and surgical patients	5	NR	NR	27.4%
Rello et al, 2002 ⁶¹⁸	Medical and surgical patients	11	40,000	NR	0%
Warren et al, 2003 ⁶¹⁹	Medical and surgical patients	25	11,897	16%	NR
Cocanour et al, 2005 ⁶²⁰	Trauma patients	15	57,158	NR	0%
Bloodstream Infection					
Pittet et al, 1994 ²⁶⁹	Surgical patients	24	40,000	NR	35%
Digiovine et al, 1999 ²⁷⁰	Medical patients	10	34,508	NR	4%
Warren et al, 2006 ⁶²¹	Medical and surgical patients	7.5	11,971	23%	NR
Catheter-Associated Urinary Tract Infection					
Bryan et al, 1984 ⁴⁷⁵	Medical and surgical patients	NR	NR	NR	12%
Tambyah et al, 2002 ⁴⁷⁸	Medical and surgical patients	NR	589	NR	NR

CABG, coronary artery bypass grafting; NR, not reported.

Studies cited in table (column 1) may be found in the complete list of references for this chapter provided online.

JCAHO mandates that all hospitals have an active program for the surveillance, prevention, and control of hospital-acquired infections, which begins with an institutional infection control committee with representation from the major clinical services and hospital departments including the institution's ICUs. The most essential members of the infection control program are the infection control practitioner(s), usually registered nurse(s), and the hospital epidemiologist, usually a physician with training in infectious diseases or microbiology, who implement the policies developed by the committee, educate hospital personnel about nosocomial infection control, and investigate suspected outbreaks (Box 50.2).

Surveillance of nosocomial infections is the cornerstone of an effective infection control program and offers numerous potential benefits^{119,124}: (1) It permits determination of baseline (expected) infection rates, assisting recognition of outbreaks and evaluation of new policies and control measures; (2) it identifies institutional problems that require attention, permitting focused infection control efforts and education; (3) it provides reliable data that can be disseminated to individual departments, increasing awareness and

involvement of individual staff members; (4) it increases the visibility of the infection control staff on patient care units, providing an opportunity for consultation and ad hoc education; and (5) it facilitates the earliest discovery of patients with communicable infections, permitting timely institution of isolation precautions to limit spread. Because total surveillance (of all infections) is labor intensive, most hospitals now focus their surveillance efforts on infections that are associated with high morbidity (e.g., nosocomial pneumonia), that greatly increase health care costs (e.g., post-cardiac surgery sternotomy infections), that are caused by antibiotic-resistant organisms with potential for spread (e.g., MRSA, *C. difficile*), or that are highly preventable (e.g., intravascular device-related bloodstream infections).^{119,125}

The 1990s were characterized by major efforts by hospitals to apply the numerous facets of health care principles of quality improvement developed by industry. Hospital infection control programs had been working on quality improvement¹²⁶ but, influenced by JCAHO, were probably too heavily focused on process, namely, policies and procedures, rather than documenting outcome vis-à-vis reduced infection rates. Infection control programs in most U.S.

Box 50.2 Facets of a Hospital Infection Control Program

- Active infection control committee, with representation from major departments and services including the intensive care units (ICUs)
- Surveillance of nosocomial infections, especially in each ICU
- Comprehensive and regularly updated institutional policies and procedures for prevention of nosocomial infection:
 - Surveillance of nosocomial infections
 - Isolation and universal precautions
 - Sterilization and disinfection
 - Indications for and management of invasive procedures and devices:
 - All types of intravascular catheters
 - Hemodynamic monitoring
 - Tracheostomy and endotracheal intubation
 - Mechanical ventilation and other respiratory therapy
 - Bronchoscopy and gastrointestinal endoscopy
 - Anesthesia and the operating room
 - Hemodialysis
 - Intra-aortic balloon pumps
 - Cardiopulmonary bypass
 - Intracranial pressure monitoring
- Antimicrobial stewardship program
- Guideline for investigation of an epidemic
- Strong liaison with clinical microbiology laboratory
 - Representation on the infection control committee
 - Laboratory-based surveillance
 - Monitoring and reporting of trends in antimicrobial susceptibility
 - Retaining important isolates
 - Microbiologic support of all infection control activities
 - Subtyping of isolates for investigations or studies
- Educational programs for new employees, periodic updates dealing with nosocomial infection control
- Active employee health department:
 - Free immunizations (hepatitis B, measles, mumps, rubella, varicella, pertussis, influenza A)
 - Tuberculin screening
 - Postexposure protocols
- Quality assurance review of implementation of infection control policies and practices

Modified from Maki DG: Nosocomial infection. In Parrillo JE (ed): Current Therapy in Critical Care Medicine, 2nd ed. Philadelphia, BC Decker, 1991.

hospitals are now closely allied with their institutional quality improvement departments.^{126,127}

Hospital infection control programs are also regulated by the Occupational Safety and Health Administration (OSHA) in terms of institutional standards and programs to protect HCWs from bloodborne pathogens¹²⁸ and tuberculosis¹²⁹; the Environmental Protection Agency¹³⁰ has also published regulations in terms of disposal and tracking of medical waste—only a small fraction of which is truly biohazardous.¹³¹

Finally, it is essential that all health care personnel working in an ICU receive training in the epidemiology and control

of nosocomial infections. This may be most important for house officers in teaching hospitals, who commonly enter the ICU with only the most rudimentary knowledge of sepsis but have hands-on contact with numerous patients each day. ICU physicians and nurses must be especially familiar with their hospitals' guidelines for the management of invasive devices, particularly intravascular catheters of all types,¹³² urinary catheters,^{133,134} endotracheal tubes,¹³⁵ and tracheostomies.¹³⁵ Moreover, all physicians need to be made aware that broad-spectrum antimicrobial therapy greatly increases the risk of superinfection by antibiotic-resistant bacteria and *Candida*, as well as *C. difficile*.

ROLE OF THE MICROBIOLOGY LABORATORY

Accurate and timely diagnostic microbiology is as essential for nosocomial infection control as it is for the clinical management of patients' infections. Although many infections can be diagnosed on the basis of clinical criteria alone, cultures and other laboratory tests allow infections to be diagnosed with much greater certainty, and certain infections such as bacteriuria, bacteremia, and fungal and viral infections cannot be diagnosed without cultures or other laboratory tests (see Box 50.1).^{16,17} Moreover, accurate antimicrobial susceptibility testing of clinical isolates is the only means of monitoring trends in antibiotic resistance of hospital organisms.¹³⁶ Most importantly, identifying the microbial cause of nosocomial infections allows epidemiologic tracking of individual pathogens within the hospital, especially those that are commonly spread from patient to patient such as *S. aureus*, beta-hemolytic streptococci, enterococci, and the numerous gram-negative bacilli.

From an organizational standpoint, the institutional infection control program and clinical microbiology laboratory must have a close working relationship (see Box 50.2) to assist surveillance, which must be strongly laboratory based,^{119,137} and to permit the detection and resolution of potential problems. The laboratory director or a senior member of the laboratory staff should be a permanent member of the infection control committee.

The primary role of the clinical microbiology laboratory in any infection control program is to provide up-to-date clinical microbiologic data for use in the surveillance of nosocomial infections and identification of potential outbreaks.¹³⁷ Protocols should be developed to ensure that laboratory staff immediately contact infection control personnel after the isolation of certain important pathogens such as MRSA or vancomycin-resistant enterococci (VRE) or the appearance of new resistance patterns in endemic organisms such as resistance of *Klebsiella* species to third-generation cephalosporins and carbapenems, or *P. aeruginosa* to aminoglycosides, fluoroquinolones, and carbapenems. Sifting through these data can be time consuming, and developing electronic information systems that streamline this process is essential to improving the efficiency of the infection control program. Commercial software programs that can automate this process are now available. Many of these programs automatically collate microbiologic data, provide rudimentary geographic information, and perform basic statistical analyses that can

assist in the surveillance of nosocomial infections and identification of potential outbreaks.^{138,139}

Reporting cumulative summaries of antimicrobial susceptibility data (antibiograms) is another essential responsibility of the clinical microbiology laboratory.^{140,141} When implemented appropriately, the timely dissemination of antibiograms helps guide the choice of empiric antimicrobials, pending the results of clinical cultures, and provides valuable data to help the infection control department monitor institutional antimicrobial resistance trends and identify potential outbreaks.¹⁴² The Clinical and Laboratory Standards Institute—formerly the National Committee for Clinical Laboratory Standards—recommends that institutional antibiograms be updated at least annually and has recently published standards for their content and format.¹⁴³ Automated electronic systems for collating and disseminating nearly real-time antibiograms along with antibiotic-use decision support exist and, when implemented properly, have been effective in improving antimicrobial utilization within the hospital setting.^{144,145}

Monitoring of sterilizers with spore tests, environmental sampling, and advanced microbiologic support for epidemiologic investigations are additional responsibilities expected of most clinical microbiology laboratories, although some university hospital programs have dedicated personnel within their infection control programs who perform these activities.¹³⁷

The clinical microbiology laboratory is a key resource in the investigation of a suspected outbreak. One of the first and foremost actions when a nosocomial outbreak is suspected is to immediately retrieve all available isolates of the putative epidemic pathogen for possible subtyping.¹⁴⁶ The need to move rapidly becomes apparent when it is realized that most hospital laboratories discard cultures as soon as the isolates have been fully characterized. All blood isolates should be routinely saved for at least 1 year.¹⁴⁶ Laboratory personnel must be requested to save clinical isolates of any unusual organisms that are encountered for the first time or clusters of any organism and to inform infection control personnel of the findings and availability of the isolates.

The rapid evolution of molecular microbiology has revolutionized epidemiologic investigation of nosocomial outbreaks. Molecular-based tests for the rapid diagnosis of bacterial,¹⁴⁷ viral,^{78,148} and fungal¹⁴⁹ infections are now routinely available in most hospital-based and reference laboratories. Modern molecular tests can reliably detect minute numbers of organisms, allowing direct testing of clinical samples without the need for culture. In modern-day clinical virology, molecular tests based on polymerase chain reaction (PCR) for amplification of the pathogen's DNA or RNA have supplanted tissue cultures and now allow rapid diagnosis of infections that would otherwise often not be identifiable by classic methods.

The availability of molecular subtyping systems has greatly strengthened investigations of outbreaks, as well as research on the epidemiology of nosocomial infections.^{150,151} The antimicrobial susceptibility pattern (antibiogram) or the detailed biochemical profile (biotype) is often useful for the initial epidemiologic subtyping of many bacteria and may be adequate for identifying an epidemic caused by an unusual pathogen. However, if an epidemic organism is a

common species such as *S. aureus*, it can be difficult or even impossible to know with certainty that an outbreak derives from a common source using these techniques because they lack sufficient discriminatory power.¹⁵⁰

The new molecular techniques of subtyping such as plasmid profile typing by agarose gel electrophoresis or the use of restriction endonuclease digests with pulsed-field electrophoresis (DNA fingerprinting)¹⁵⁰ are now available in most infection control research laboratories but should be adaptable by many hospital laboratories. Genetic probes promise even more powerful tools for investigating outbreaks, particularly those caused by antibiotic-resistant organisms.¹⁴⁷

Although molecular-based tests offer several advantages over traditional microbiologic techniques, they are not a panacea. A number of molecular diagnostic assays (e.g., analyte specific reagents [ASRs]) marketed for clinical practice do not require approval by the U.S. Food and Drug Administration.¹⁴⁷ In the absence of published data on their accuracy and precision, the results of these tests must be interpreted with caution and should always undergo extensive inhouse validation before widespread adoption. Moreover, the exquisite sensitivity of many of these tests renders them more susceptible to false-positive results as a consequence of environmental contamination^{152,153} and mandates stringent quality control practices and procedures.

ARCHITECTURAL AND ENVIRONMENTAL ISSUES

The role of the inanimate environment on the transmission of nosocomial infections has been a subject of intense debate for decades. It has been shown that hospital surfaces are almost universally contaminated by potentially pathogenic bacteria such as *S. aureus*,¹⁵⁴ enterococcus,¹⁵⁵ and gram-negative bacilli such as *Acinetobacter baumannii*.¹⁵⁶ Prior to the 1970s, infection control personnel routinely sampled hospital surfaces. Despite this level of surface colonization, early studies found that the inanimate environment—surfaces, walls, and even air—does not contribute materially to the occurrence of most nosocomial infections,¹⁵⁷ other than invasive infections caused by airborne *Aspergillus* and other filamentous fungi in seriously immunocompromised patients.^{40,41}

Although inanimate surfaces may rarely be involved in the direct transmission of infection to patients, more recent evidence suggests that surfaces may well play an important role in the nosocomial acquisition of pathogenic bacteria, indirectly, through contact with HCWs' hands and equipment (see Fig. 50.3). This indirect route of infection is of particular importance in the ICU, where all patients are heavily exposed to invasive devices and have a high risk of infection. In the ICU the inanimate environment may become a reservoir for the transmission of resistant nosocomial organisms such as MRSA,^{158,159} *C. difficile*,^{83,160} VRE,^{155,161} and gram-negative bacilli such as *Klebsiella* spp., *Acinetobacter* spp., and *Enterobacter* organisms.^{162,163} Studies have shown that enhanced surface decontamination with hypochlorite-containing cleaning solutions has been necessary to terminate outbreaks caused by *C. difficile*¹⁶⁴ and *Acinetobacter baumannii*.¹⁵⁶

Although the ICU environment cannot be made microbe free, certain organizational, architectural, and environmental issues must be addressed with the design or remodeling of an ICU. The capacity to systematically improve the care of critically ill patients and prevent nosocomial infection requires a structural foundation on which the processes of care can be optimized (i.e., make it easy for HCWs to do it right and difficult to do it wrong). Accountability for compliance with critical policies and procedures and ongoing assessment of outcomes needs to be built into the administrative structure of the ICU.

An ICU must be adequately staffed to allow the processes of care to be carried out but also assure a high level of compliance with essential infection control measures such as hand hygiene and barrier isolation. Adequate staffing cannot be overemphasized; numerous studies have found greatly increased rates of nosocomial infection when ICUs are staffed suboptimally or when staffing requirements are met with temporary personnel who are unfamiliar with ICU infection control policies and procedures.^{165,166} In a large nosocomial outbreak of *Enterobacter cloacae* infection in a neonatal ICU, Harbarth and colleagues¹⁶⁷ found that infection rates during periods of understaffing were strikingly higher than during periods with adequate levels of staffing (relative risk [RR] = 6, 95% confidence interval [CI] = 2.2 to 16.4). The effects of understaffing are likely multiple; however, erosion of basic hygienic practices with excessive patient-to-staff ratios likely explains much of this phenomenon.¹⁶⁸

Many of the published recommendations for ICU architectural design¹⁶⁹ are empiric, and evidence that they reduce rates of nosocomial infection is, by and large, lacking. Although more research is necessary before specific features of ICU design achieve a level of evidence sufficient for an evidence-based guideline, certain facets of the ICU layout deserve attention:

- ICUs should be located in areas that limit traffic flow to essential ICU personnel.
- ICU facilities should be designed with ICU professionals in mind, ensuring appropriate space, resources, and environment for day-to-day operations.¹⁶⁹ Recognizing the growing variety and complexity of life support equipment required for the care of many patients, each cubicle or room should provide a minimum of 11 m² per bed.¹⁷⁰ The area should be large enough to accommodate the bed and all equipment yet allow immediate access to the patient at all times from both sides of the bed. Adequate space must also be provided for storage of nursing supplies. Facilities for disposal of biohazardous waste (e.g., bedpan flushers); for cleaning, reprocessing, and storage of ICU equipment; and for storage of housekeeping supplies should be separate from patient care areas. Single-patient rooms may increase the likelihood of handwashing being done and improve compliance with isolation practices, reducing the risk of cross-infection. For example, Mulin and colleagues¹⁷¹ found that converting from an open unit to single rooms in their ICU greatly reduced rates of patient colonization with *A. baumannii*, and Shirani and colleagues¹⁷² found that renovation of their burn unit to include separate bed enclosures reduced rates of nosocomial infection by 48%.¹⁷²

- Materials used for fixtures, furniture, and other surfaces should be smooth and easy to clean; surfaces made of porous materials foster bacterial colonization.¹⁷³
- An adequate number of sinks must be available for convenient handwashing by ICU personnel. Ideally, a sink should be located at the *entrance* of each cubicle or patient room to encourage handwashing by all entering personnel who will have contact with the patient or the immediate environment.^{174,175} Separate sinks should be used for cleaning and reprocessing contaminated equipment. Sinks and sink drains are normally contaminated by pseudomonads,¹⁷⁶ although their role in the epidemiology of nosocomial infection is as yet unclear. However, sinks should be designed to minimize aerosol formation and splashback.
- All ICUs should be equipped with one or more class A isolation rooms, which include an anteroom for gowning and handwashing and the necessary modifications (negative pressure, roofline exhaust) to permit it to be used for patients with tuberculosis or other airborne infections such as chickenpox, measles, disseminated HSV infection, or a highly contagious emerging pathogen such as the severe acute respiratory syndrome (SARS) human coronavirus. If an ICU treats bone marrow transplant patients or other patients with prolonged severe granulocytopenia, positive-pressure isolation rooms using high-efficiency particle-arrest (HEPA) filters should be available. Isolation rooms for patients with infections transmitted by the respiratory route or to protect profoundly granulocytopenic patients must be kept closed to maintain control over the direction of airflow.
- A centralized, filtered air-handling system that provides at least six room exchanges per hour is essential.^{170,177} Ideally, each patient's room should have the capacity of being set at positive or negative pressure with respect to the rest of the unit; if it cannot be, the room should be maintained permanently at positive pressure.

A variety of microorganisms including bacteria, mycobacteria, fungi, and parasites can be isolated from hospital water and have been implicated in endemic and epidemic nosocomial infections.¹⁷⁸ Many of these outbreaks were caused by bacteria typically thought of as “water” organisms such as *P. aeruginosa*,¹⁷⁶ *Stenotrophomonas maltophilia*,¹⁷⁹ and *A. baumannii*;^{16,180,181} however, the most important and epidemiologically linked hospital water pathogen is the *Legionella* group.¹⁸²

Nosocomial legionellosis was first described in 1979,¹⁸³ and it is estimated that up to 50% of cases of legionellosis are acquired in the health care setting¹⁸⁴ with a mortality rate that approaches 30%.¹⁸⁵ Contamination of hospital potable water remains underappreciated despite studies showing that *Legionella* species can be recovered from 12% to 70% of hospital water systems,¹⁸⁶ and a number of studies in which nosocomial cases were identified only when specific diagnostic and surveillance methods were employed.^{187,188} Characteristics of hospital water systems that are associated with *Legionella* contamination include piping systems with dead-ends that facilitate stagnation, large-volume water heaters that result in inefficient heating of hospital water, sediment buildup, water heater temperatures

less than 60°C and tap water temperatures less than 50°C, maintaining water pH greater than 8 and receiving municipal water untreated with monochloramine.¹⁸⁹⁻¹⁹¹

Despite the ubiquity of water systems colonized with *Legionella* species and studies demonstrating a correlation between the level of colonization and risk of infection, the CDC does not recommend routine surveillance of hospital water systems,¹⁸⁴ although this stance is controversial.¹⁸⁶ Researchers from Pittsburgh, Pennsylvania, and the Allegheny County Health Department have recommended a more proactive stepwise approach that involves initial surveillance of hospital water for *Legionella* contamination, regardless of the presence or absence of institutional nosocomial legionellosis, followed by continued surveillance based on the level of water contamination found or the presence of institutional legionellosis.¹⁸⁶

Legionella species are resistant to chlorine and heat, making it challenging to eradicate them from contaminated hospital water systems.¹⁹¹ Attempts to hyperchlorinate hospital water have been partially successful if chlorine levels are continuously maintained between 2 and 6 parts per million at all times but produce rapidly accelerated corrosion of water pipes and are expensive.¹⁹² Thermal eradication is feasible, using a “heat-and-flush” method to raise water tank temperatures to greater than 70°C and distal water sites to greater than 60°C for short periods of time.¹⁹³ Although effective, superheating is labor intensive and there is the constant fear that patients or health care personnel may sustain scald injuries if they wash or shower with tap water during a flushing period. The use of technologies such as instantaneous steam heat for incoming water¹⁹³ and ultraviolet light¹⁹⁴ are technically feasible with newer hospital water systems but may be incompatible with older hospital water systems.

Perhaps the most attractive, effective, safe, and cost-efficient method for *Legionella* eradication may be the use of continuous copper-silver ionization systems to sterilize hospital water systems. These systems have been well studied over the past decade and have proved to be highly effective for reliably eradicating *Legionella* contamination of hospital water and, most importantly, for eliminating nosocomial legionellosis in institutions when other interventions have failed.¹⁹⁵ In our own institution (Maki DG), two clusters of nosocomial legionellosis prompted a retrospective review that identified 10 cases over an 11-year period. Surveillance of the hospital water system found that 75% of all samples contained low levels of *L. pneumophila*, which were shown to be clonally related to the 10 cases of nosocomial legionellosis. Installation of a continuous copper-silver ionization system led to complete eradication of *Legionella* from water samples, and no further cases of nosocomial legionellosis have been identified at our institution since 1995, among 255,000 patients hospitalized.

RELIABLE STERILIZATION PROCEDURES, CHEMICAL DISINFECTANTS, AND ANTISEPTICS

Reliable sterilization, disinfection, and antisepsis embrace virtually all measures aimed at prevention of nosocomial

infection. *Critical* objects, which are introduced directly into the bloodstream or into other normally sterile areas of the body, such as surgical instruments, cardiac catheters, and implanted devices, must be reliably sterile and sterilized with steam, gas, hydrogen peroxide gas, or chemical sterilization. *Semicritical* items, which come into contact with intact mucous membranes, such as fiberoptic endoscopes, endotracheal tubes, or ventilator circuit tubing, can be decontaminated between patients by pasteurization or the use of high-level chemical disinfection with glutaraldehyde, peracetic acid, hydrogen peroxide, ethyl alcohol, or hypochlorite. *Noncritical* items, which normally come into contact only with intact skin, such as blood pressure cuffs or electrocardiograph electrodes, require hygienic cleansing or low-level disinfection with an iodophor, hypochlorite, quaternary ammonium or phenolic disinfectants, or alcohol.^{196,197} The lone exception to this classification scheme is devices that pose a risk of transmitting prion-related diseases, including Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD).^{198,199} Prions are not readily inactivated by conventional disinfection and sterilization procedures.^{196,199} As a result, devices that pose a risk for transmission of prion-related diseases should undergo special sterilization procedures after cleaning that involve sodium hydroxide followed by low-temperature autoclaving (121°C) or high-temperature autoclaving (132°C for 1 hour or 134°C for ≥18 minutes).^{197,199} Despite concerns that procedures involving semicritical items such as endoscopes and bronchoscopes may pose a risk for transmission of prion-related infections, there has not been a single report of CJD or vCJD associated with these devices. As a result, current guidelines recommend that only critical items and semicritical items that have come in contact with neurologic tissue (e.g., brain [including dura mater], spinal cord, eye, and pituitary tissue) should undergo special prion inactivation sterilization procedures.^{197,199,200}

Numerous epidemics of gram-negative infection have been described in association with respiratory therapy equipment,^{97,98} diagnostic equipment such as bronchoscopes and endoscopes,^{98,102-104} and solutions used for cutaneous antisepsis.^{201,202} Most of these outbreaks were traced to improper procedures or malfunction of automated systems used for the disinfection and sterilization of medical devices, although a number of epidemics in years past arose as a result of extrinsic contamination of solutions used for cutaneous antisepsis.^{201,202} For these reasons, the importance of strict adherence to recommended policies and procedures for cleaning and reprocessing medical equipment used in the ICU cannot be overemphasized.

Endoscopes and bronchoscopes are essential diagnostic and therapeutic instruments in the ICU. Although most postendoscopy nosocomial infections are caused by inoculation of colonizing mucosal flora into normally sterile, vulnerable anatomic sites during the procedure, numerous epidemics have been traced to contaminated endoscopes.^{98,102-104} Following use for bronchoscopy, endoscopes are typically contaminated with 6×10^4 colony-forming units per milliliter (CFUs/mL).²⁰³ All endoscopes are considered semicritical medical devices by the Spaulding classification

and therefore require high-level disinfection following use.²⁰⁰ In order to ensure their safe use, flexible endoscopes should be reprocessed with the following procedures: (1) physical cleaning to reduce microbial bioburden and remove organic debris; (2) high-level disinfection—glutaraldehyde and automated chemical sterilizing systems that use peracetic acid are most commonly used in the United States—with adequate contact time between the disinfectant and device surface; (3) following disinfection, rinsing with sterile or filtered tap water to remove disinfectant residue; (4) flushing of all channels with 70% to 90% ethyl or isopropyl alcohol; and (5) drying with forced air.²⁰⁰ Devices used with endoscopes that violate mucosal barriers, such as biopsy forceps, need to be reprocessed as critical medical items with full sterilization.²⁰⁰ Other devices used in the delivery of respiratory care are also considered semicritical under the Spaulding classification and therefore should be reprocessed in a manner similar to endoscopes prior to reuse.¹³⁵

Iodophors (e.g., 10% povidone-iodine), until recently, have been the most common agents used for cutaneous disinfection in North America. However, a large, prospective, randomized trial of cutaneous antiseptics used for drawing blood cultures showed that chlorhexidine was superior to 10% povidone-iodine and was associated with a more than twofold reduced rate of contaminated blood cultures (odds ratio [OR] = 0.40, 95% CI 0.21 to 0.75, $p = 0.004$).²⁰⁴ Moreover, a meta-analysis examining the impact of different cutaneous antiseptic agents found that chlorhexidine was superior to povidone-iodine for both the prevention of intravascular catheter colonization and catheter-related bloodstream infection.²⁰⁵ On the basis of these and other recent studies,^{206,207} chlorhexidine-containing solutions are the preferred cutaneous antiseptics for insertion of intravascular devices in the ICU.¹³² Whatever agent is used, it is essential that it be applied with vigorous scrubbing for a minimum of 1 minute to allow adequate time for germicidal activity.

HAND HYGIENE

The major reservoir of nosocomial infection in the ICU is infected or colonized patients, and the major mode of spread of most nosocomial bacterial pathogens, many viruses, and even *Candida* from patient to patient is by transient carriage on the hands of medical personnel (see Fig. 50.3). Studies of hand carriage of nosocomial pathogens by ICU personnel, using a simple rinse technique to quantify the transient flora,²⁰⁸ have shown that, on average, approximately 60,000 CFUs (or 4.6 logs) are recovered from the hands of ICU personnel randomly sampled (Table 50.4). Nearly half of persons cultured at any point in time will be found to be carrying gram-negative bacilli, and 10% will be carrying *S. aureus*.²⁰⁹ Serial culturing has shown that all ICU personnel, at various times, carry gram-negative bacilli and that nearly two thirds carry *S. aureus*. Carriage of both gram-negative bacilli and *S. aureus* is typically transient: sampling persons every other day over a prolonged period has shown *S. aureus* or the same gram-negative species in consecutive cultures only 16% of the time; prolonged carriage of a single gram-negative species seems to be rare—but has been reported.²¹⁰

Hygienic handwashing before undertaking invasive procedures, handling open wounds, or having manual contact with high-risk patients (e.g., newborns or patients in ICUs) or after touching a source or object likely to be contaminated has been recognized since the time of Semmelweis and Lister as one of the most basic and important infection control measures. Despite universal acknowledgment of handwashing as a cornerstone of nosocomial infection control programs, compliance rates much above 50% have been difficult to achieve, and handwashing rates among HCWs have ranged from 9% to 50% in numerous observational studies.^{168,211,212} Recent investigations have undertaken to better understand the reasons for poor compliance in the face of the compelling evidence that hand hygiene is essential for prevention of nosocomial infection,¹⁶⁸ identifying cutaneous irritation, inconvenient sink location,

Table 50.4 Studies of Microorganisms Carried on the Hands of Hospital Personnel Working in a Neurosurgery Unit*

Study Parameter	All Microorganisms	Gram-Negative Bacilli	<i>Staphylococcus aureus</i>

time constraints, high workload, and understaffing. Of concern, risk factors for noncompliance with hand hygiene include being a physician (rather than a nurse); working in an ICU; and paradoxically, engaging in patient-care activities with a high risk of cross-transmission.¹⁶⁸ Interventions to redress these deficiencies have included targeted education; feedback; convenient location of sinks and hand hygiene agents; use of alternative, less irritative hand hygiene agents; hand care lotions or creams²¹³; and patient education.²¹⁴

Studies done with working hospital staff have shown that hygienic handwashing with an antiseptic-containing agent reduces the count of microorganisms on the hands of the user far more effectively than handwashing with a nonmedicated soap.²⁰⁸ Repeated use of some antiseptics such as chlorhexidine has a cumulative suppressive effect on the transient hand flora. Routine use of an antiseptic-containing handwashing agent could, in theory, enhance the effectiveness of the handwashing that is done. Moreover, if an agent that exhibits prolonged antimicrobial activity, such as chlorhexidine, is used, it might also confer protection against contaminants acquired between handwashings.²⁰⁸ However, antiseptic-containing handwashing agents are more expensive and often more irritating to the skin. Irritation can result in dermatitis and, paradoxically, increased colonization by gram-negative bacilli.²¹⁵

Clearly, antiseptic-containing soaps are more effective in removing microorganisms from the hands of users, but will routine use of these agents for hygienic handwashing reduce the incidence of nosocomial infection in patients? Discontinuation of hexachlorophene for handwashing by personnel and bathing of infants in the United States in 1973 was followed by a marked upsurge in *S. aureus* infections in nurseries,²¹⁶ and use of chlorhexidine-containing handwashing agents was considered an essential measure for control of hospital outbreaks caused by multiply resistant *Klebsiella*²¹⁷ and MRSA.^{218,219} However, since Semmelweis's study, few studies have prospectively evaluated the efficacy of antiseptic-containing handwashing agents for reducing endemic nosocomial infections, particularly infections caused by gram-negative bacilli.^{215,220}

In 1982 a comparative sequential trial of three handwashing agents—a nonmedicated tissue soap, 10% povidone-iodine (Betadine Scrub), and 4% chlorhexidine (Hibiclens)—was undertaken in the trauma-surgical ICU of the University of Wisconsin Hospital.²¹⁵ Each agent was used exclusively for approximately 6 weeks, during which time hand cultures of ICU personnel were done at random and surveillance of infection in patients was carried out. Risk factors for infection in patients hospitalized during the use of each agent were comparable: Nearly two thirds of the patients in each period required ventilatory support and hemodynamic monitoring, and almost all had urinary catheters. The incidence of nosocomial infection in all groups was expectedly high, but it was 30% lower during the use of the two antiseptic-containing handwashing agents than during the use of the nonmedicated soap ($p < 0.001$). Povidone-iodine was irritating to the hands of most staff, and chlorhexidine had a slightly drying effect but was well tolerated, comparable with the nonmedicated soap.

In a similar study at the University of Iowa Hospital, Massanari²²⁰ did not find significant differences in the rates of nosocomial infection when nonmedicated soap was used exclusively as compared with alternating cycles during which 4% chlorhexidine (Hibiclens) was used in surgical ICUs; however, the incidence of infection in the medical ICU was 50% lower during use of chlorhexidine ($p < 0.05$).

In the largest multiple-crossover prospective study—1894 adult patients in three ICUs—of the relative efficacy of antiseptic-containing handwashing agents used by personnel in ICUs, Doebbeling and colleagues²²¹ found that the use of 4% chlorhexidine (Hibiclens) was associated with a 30% reduction in nosocomial infections (OR = 0.73), as contrasted with rates when a 60% alcohol hand-rinsing agent (Cal-Stat) was used. Both regimens were well tolerated.

Recently, alcohol-based waterless hand rubs have become the agents of choice for hand hygiene and are now universally used in U.S. hospitals because of their convenience and broad-spectrum activity.²¹⁴ Alcohols have the most rapid and pronounced bactericidal action and greatly reduce the time needed for hand disinfection. A vigorous 1-minute rubbing with a sufficient volume of alcohol to wet the hands completely has been shown to be highly effective at reducing the density of skin flora.²²² Ethanol and iso- and *n*-propanol are the constituents of most commercially available alcohol-based hand rubs; at equal concentrations, *n*-propanol is most effective and ethanol the least. However, all have limited efficacy with gross soilage so that visibly soiled hands should always be washed with antiseptic soap and water.¹⁷⁴ Moreover, at least 3 mL of an alcohol-based rub is necessary to completely coat the hands and achieve optimal degerming. The use of alcohol hand rubs or gels will be augmented by making conveniently located calibrated dispensers widely available. However, many HCWs prefer individual containers that can be carried in a pocket, which makes it difficult to ensure that an adequate volume is used with each application.

Few trials have been conducted to evaluate the efficacy of alcohol-containing hand rubs for reducing nosocomial infection. Most are quasi-experimental before-after studies, and most have shown a short-term reduction in nosocomial infection rates with use of alcohol-containing hand rubs.^{175,223,224}

The major factor limiting acceptance of alcohol products for hand antisepsis in the past was desiccation and irritation of skin. This is now obviated by incorporating emollients into alcohol-based hand rubs, which has enhanced acceptance by HCWs and may augment antibacterial activity by slowing the evaporation of alcohol.²²⁵ A recent randomized clinical trial in 50 ICU HCWs compared a conventional 2% chlorhexidine gluconate wash with water to a waterless alcohol-based hand rub (61% ethanol with emollients) and showed that use of the waterless alcohol-based product produced significantly less skin scaling and irritation²²⁶; unfortunately, degerming was not assessed.

A recent review describes in detail the various hand hygiene agents available and their spectrum of activity.²¹⁴ Recommendations for hand hygiene by the CDC have been published (Table 50.5),¹⁷⁴ emphasizing hand

Table 50.5 Recommendations for Routine Hand Hygiene from the Centers for Disease Control and Prevention (CDC) Guideline

Recommendation	Level of Evidence*
<ul style="list-style-type: none"> When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a nonantimicrobial soap and water or an antimicrobial soap and water. 	IA
<ul style="list-style-type: none"> If hands are not visibly soiled, use an alcohol-based hand rub or, alternatively, wash hands with an antimicrobial soap and water, for the following situations: <ul style="list-style-type: none"> Before direct contact with patients Before putting on sterile gloves when inserting a central vascular catheter Before inserting a urinary catheter, peripheral vascular catheter, or other invasive procedure not requiring surgery After contact with patient's intact skin (e.g., while taking a pulse or blood pressure or lifting the patient) After contact with body fluids, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled Moving from a contaminated body site to a clean body site during patient care After contact with inanimate objects (e.g., medical equipment) in the immediate vicinity of the patient After removing gloves 	IB
<ul style="list-style-type: none"> Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with an antimicrobial soap and water. 	IB
<ul style="list-style-type: none"> Antimicrobial-impregnated wipes are not a substitute for using an alcohol-based hand rub or antimicrobial soap. 	IB
<ul style="list-style-type: none"> If exposure to <i>Bacillus anthracis</i> is suspected or proved, wash hands with nonantimicrobial soap and water or antimicrobial soap and water. 	II

*Categorization of recommendations: IA: strongly supported for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. IB: strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale. IC: required for implementation, as mandated by federal or state regulation or standard. II: suggested for implementation and supported by suggestive clinical or epidemiologic studies or by strong theoretical rationale. NR (no recommendation/unresolved issue): practices for which insufficient evidence or no consensus exists about efficacy.

Data from Boyce JM, Pittet D: Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. MMWR Recomm Rep 2002;16:1-45.

antisepsis with an antiseptic-containing soap or detergent or an alcohol-based hand rub (1) before and after direct contact with patients or the environment and equipment in the immediate vicinity of the patient and (2) before performing invasive procedures such as insertion of an intravascular device or urinary catheter. Use of skin care products—lotions or creams—to minimize irritant contact dermatitis associated with frequent handwashing and improve compliance with hand hygiene practices is highly recommended.

Institutional commitment is essential to improve compliance with recommended hand hygiene practices. The CDC guideline recommends that institutions (1) monitor and record adherence to hand hygiene by ward or service; (2) provide feedback to HCWs about their performance; and (3) monitor the volume of alcohol hand rubs used per 1000 patient-days.¹⁷⁴

Clearly, further studies are necessary, particularly large comparative trials in which rates of nosocomial infection, rather than levels of cutaneous colonization, are used as the index of comparison. In the meantime the available data indicate that routine use of a chlorhexidine-containing product or alcohol-containing product will be more effective than use of a nonmedicated soap for hand hygiene in the high-risk areas of the hospital, such as ICUs, where cross-infection is most likely to occur.

ISOLATION PRECAUTIONS FOR COMMUNICABLE INFECTIONS

Isolation, the use of special precautions in the care of infected patients, is the only means of curtailing the spread of contagious microorganisms and preventing epidemics, especially in ICUs, where the risk of cross-infection is highest. Although requiring all persons entering an infected patient's room to wear gloves and a gown, possibly even a mask, may seem ritualistic and almost archaic, each aspect of the isolation procedure is directed at interrupting a potential mode of spread and is based on the known epidemiology of the infecting organism.²²⁷ To be maximally effective, however, isolation procedures require compliance by each person coming into contact with the patient, including physicians. Isolation is also indicated, usually for the entirety of hospitalization, for all patients infected or known to be colonized by antibiotic-resistant nosocomial pathogens such as MRSA, multidrug-resistant gram-negative bacilli, or VRE; in such cases, isolation has been shown to be effective in reducing endemic infections^{228,229} (Figs. 50.3 and 50.4) and in controlling outbreaks.²²⁹

ISOLATION SYSTEMS

Most U.S. hospitals subscribe to one of two CDC isolation systems developed by panels of experts. The simplest system,

Figure 50.3 Impact of implementing barrier-type precautions (gown and gloves) with patients known to be colonized or infected by gram-negative bacilli resistant to gentamicin. Frequency of infections by gentamicin-resistant gram-negative bacilli and gentamicin use at Michael Reese Medical Center, 1970-1977. Data are plotted as the monthly average, and the averages for the first 7 and last 5 months of 1974 are plotted separately to demonstrate the effect of barrier-type precautions implemented in August 1974. *EKES*, *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter* species, and *Serratia* species. (From Weinstein RA, Nathan C, Gruensfelder R, et al: Endemic aminoglycoside resistance in gram-negative bacilli: Epidemiology and mechanisms. *J Infect Dis* 1980;141:338-345.)

Figure 50.4 Impact of specific control measures on an institutional outbreak of vancomycin-resistant *Escherichia faecium*. Cases, by date of first positive culture for the epidemic strains (from January 1991 to December 1992). Number of cases = case patients in the intensive care unit (ICU) at time of first positive culture for the epidemic strain \times other patients with previous exposure to the ICU \times case patients never in the ICU. (From Boyce JM, Opal SM, Chow JW, et al: Outbreak of multidrug-resistant *Enterococcus faecium* with transferable vanB class vancomycin resistance. *J Clin Microbiol* 1994;32:1148-1153.)

category-specific isolation precautions, issued by the CDC in 1970,²²⁷ groups diseases in seven categories by infections for which similar precautions are indicated: wound and skin precautions, enteric precautions, discharge precautions, blood precautions, respiration isolation, strict isolation, and protective isolation. Guidelines for disease-specific isolation precautions, issued in 1983,²³⁰ consider each infectious disease individually, so only those precautions indicated to interrupt transmission of that specific disease are used. Disease-specific precautions minimize unnecessary isolation

procedures; however, they are more complicated and may be implemented most effectively by a computerized system.

An alternative, simpler system, *body substance isolation*, has gained adherents and focuses on the isolation of potentially infectious body substances, such as blood, feces, urine, sputum, wound drainage, and other body fluids, of all patients through the use of simple barrier precautions—primarily gloves, gowns, plastic aprons, and masks or goggles. These barriers should be used when potentially infectious secretions are likely to soil or splash the clothing, skin, or

face of the HCW.²³¹ Body substance isolation provides sufficient flexibility to augment the basic precautions taken with each patient, as needed, and adds private rooms with masks for infections transmitted by the airborne route. A criticism of this simpler system has been the reduced emphasis on handwashing when gloves are removed.²³²

The most recent CDC guideline¹⁷⁷ separates basic precautions into (1) *standard precautions* designed for the care of all patients in hospitals, regardless of their diagnosis or presumed infection status, and (2) additional *transmission-based precautions* designed for the care of specified patients who are known or suspected to be infected with highly transmissible or epidemiologically important pathogens. Standard precautions synthesize the major features of universal blood and body fluid precautions and are designed to reduce the risk of transmission of microorganisms from patient to patient and from patient to HCW, from both recognized and unrecognized sources of infection in the hospital. Transmission-based precautions are divided into three subgroups on the basis of the mode of transmission: contact precautions, droplet precautions, and airborne precautions. Contact precautions are recommended with multidrug-resistant bacteria that can be acquired by contact with the colonized patient or environmental surfaces or objects. Droplet precautions provide additional measures for transmission by large-particle droplets, such as during suctioning or bronchoscopy. Airborne precautions are added to standard precautions for the care of patients with tuberculosis and other microorganisms transmitted by the airborne route. In general, transmission-based precautions usually specify a private room—always for airborne precautions.

SPECIAL ISSUES IN THE ICU

An environmental issue pertaining to isolation may be most relevant in the ICU, namely, the greater potential for fomites or environmental surfaces to contribute to the spread of nosocomial infection, especially with antibiotic-resistant microorganisms. Although previous studies have not been able to demonstrate that the inanimate hospital environment, particularly surfaces, walls, or floors, contribute materially to the occurrence of nosocomial infection,^{157,158} accumulating evidence suggests that this may not necessarily be true for ICUs, where uniform exposure to invasive devices makes patients unduly susceptible. A number of careful studies of the epidemiology of ICU-acquired infection with resistant organisms such as MRSA,^{158,159} *C. difficile*,^{83,160} and VRE^{155,161,233} have shown heavy contamination of the inanimate environment immediately contiguous to the patient by strains implicated in nosocomial infections occurring in patients. Even if gloves are being worn as part of protective isolation or universal precautions, the possibility of transmission of microorganisms from the environment to patients on the gloved hands of HCWs is real. Prolonged wearing of gloves in the ICU, which is common, may increase the risk of nosocomial cross-infection, expanding the epidemiologic role of the inanimate environment with certain pathogens such as MRSA or VRE.²³³

Similarly, the use of common stethoscopes, sphygmomanometers, or electronic thermometers with multiple patients provides further opportunity for organisms to spread.

Although stethoscopes are commonly contaminated by nosocomial organisms,²³⁴ their role in cross-infection is less clear.²³⁴ On the other hand, spread of VRE²³⁵ and *C. difficile*²³⁶ has been traced to contamination of electronic thermometers. All surfaces contiguous to the ICU patient should be wiped down with the general hospital disinfectant at least daily, and each ICU patient should have a dedicated stethoscope and sphygmomanometer. The use of electronic temperature measuring devices on multiple patients within an ICU bears reevaluation, unless stringent efforts are made to assure reliable decontamination of the device after each use.

As discussed, many nosocomial infections appear to derive from organisms carried on the hands of ICU personnel, who during the working day have contact with multiple patients. To improve nursing care and reduce the risk of cross-infection, ICUs must have an adequate number of staff. Although the optimal nurse/patient ratio for patients in an ICU is not known, increased rates of infection and outbreaks have occurred when nurses have been assigned to multiple critically ill patients who require complicated nursing care.¹⁶⁶ One-to-one nurse/patient ratios may significantly reduce the risk of cross-infection.

To contain the spread of certain resistant organisms in the ICU (e.g., MRSA, VRE), cohort nursing is strongly recommended. In cohort nursing, the care of patients known to be infected (or colonized) by the organism is provided by nurses (and respiratory therapists) who will not provide care during that shift for noninfected patients, and the nursing care of noninfected patients is restricted to personnel who will not have contact with infected patients, except in an emergency. Cohorting of patients known to be colonized or infected with MRSA is widely practiced but has not been adequately studied. In one recent prospective study, the authors found that there was no evidence of increased transmission of MRSA when patients were not cohorted.²³⁷

TUBERCULOSIS

The upsurge in tuberculosis since 1985, particularly the numerous nosocomial outbreaks caused by multidrug-resistant strains,^{73-75,238,239} demonstrates the importance of isolation precautions to prevent the spread of tuberculosis within hospitals, especially within ICUs.¹²⁹ Guidelines¹²⁹ reemphasize the importance of air control by mandating the use of private negative-pressure rooms, combined with the use of ultraviolet lights or ventilatory modifications in which all air exiting the room is either filtered or exhausted directly to the roofline, away from hospital intake vents. Isolation room doors must be kept closed to maintain control over the direction of airflow, and all persons who enter a room in which tuberculosis isolation precautions are in effect must wear a disposable particulate respirator such as a dust-mist mask or a HEPA-filter mask. Gowns and gloves usually are not indicated. All ICUs should have one or more negative-pressure isolation rooms for the care of patients requiring respiratory isolation for tuberculosis and other airborne infections such as chickenpox or disseminated herpes zoster, disseminated HSV infection, or emerging, highly contagious airborne infections such as SARS. To reduce the risk of contaminating a ventilator or discharging *M. tuberculosis* into the environment, when

mechanically ventilating a patient with suspected or confirmed pulmonary tuberculosis, a bacterial filter capable of filtering particles as small as 0.3 μm , with a filter efficacy of greater than 95%, should be placed on the patient's endotracheal tube or at the expiratory side of the breathing circuit of a ventilator.¹²⁹ ICU patients with tuberculosis not requiring mechanical ventilation should wear a surgical mask if leaving the negative-pressure isolation rooms for radiographic or other procedures.¹²⁹

STANDARD PRECAUTIONS

The world epidemic of AIDS and evidence that more than 1 million persons in the United States are silent carriers of the human immunodeficiency virus (HIV) have engendered great concern among HCWs regarding the risk of exposure to HIV in the workplace. In 1987 the CDC and the Department of Labor issued detailed guidelines for *Universal Blood and Body Fluid Precautions*^{240,241} to prevent exposure of HCW workers and patients to potentially hazardous blood or body fluids. Universal precautions were based on the concept that all blood and body fluids that might be contaminated with blood should be treated as infectious because patients with bloodborne infections can be asymptomatic or unaware they are infected. The relevance of universal precautions to other aspects of disease transmission was recognized, and in 1996 the CDC expanded the concept and changed the term to *Standard Precautions*.²⁴² Standard precautions integrate and expand the elements of universal precautions into a standard of care designed to protect health care personnel and patients from pathogens that can be spread by blood or any other body fluid, excretion, or secretion. Standard precautions apply to contact with (1) blood; (2) all body fluids, secretions, and excretions (except sweat), regardless of whether they contain blood; (3) nonintact skin; and (4) mucous membranes.

Gloves are recommended for venipunctures, insertion of intravascular devices, and whenever it can be anticipated that the hands could become contaminated by blood or another high-risk body fluid. If there is potential for splatter or contamination of clothing, a gown is added. When there is potential for aerosolization of body fluids, such as during surgery, intubation, endoscopy, or insertion of an arterial catheter, a mask and eye shielding are included. Because the vast majority of occupationally related HIV infections have involved needle sticks or other sharps injuries, every effort must be made to avert such injuries that could result in percutaneous inoculation of HIV or other bloodborne viruses.^{240,243}

Because prophylactic use of barrier precautions appears to be of some benefit for the prevention of nosocomial infection^{172,244,245} and all U.S. hospitals are currently mandated to follow standard precautions, it has been suggested that the use of gloves for all patient contacts, as is now common in many U.S. hospitals, should implicitly reduce the risk of nosocomial infection in general. However, this has not been demonstrated and there is concern that standard precautions might paradoxically increase the risk of nosocomial cross-infection.²⁴⁶ In most U.S. hospitals it is still common to observe ICU personnel, many of whom routinely wear gloves for all patient contacts to protect themselves, put on gloves, touch heavily contaminated areas (e.g.,

an open wound or tracheostomy), and then, without removing the gloves, proceed to write in the patient's chart, answer the telephone, or care for another patient. This occurs because the health care providers have forgotten that although the gloves may protect themselves, the gloves must be immediately discarded after use to prevent cross-contamination of hazardous pathogens to other vulnerable sites on the same patient or transmission to other patients or the ICU environment. Before the era of AIDS and universal precautions, health care professionals were oriented toward protecting the patient and likely to wash their hands when exposed to potential contamination. Now the focus is centripetal, and many HCWs unfortunately view all precautions as measures to protect themselves. Thus prolonged wearing of gloves can result in heavy contamination of the gloves²⁴⁷ and increase the risk of nosocomial cross-infection among patients.^{233,248} It also puts the HCW at increased risk of dermatitis and allergic reactions to glove material.²⁴⁹ Standard precautions do not obviate the need for designated isolation precautions for patients with communicable infections. The greatly expanded use of gloves as part of standard precautions in hospitals must now be accompanied by educational programs on how to use gloves effectively and in a manner that will not jeopardize patients. Staff must be strongly encouraged to wash their hands after removing gloves, especially after performing a bloody procedure, because blood often penetrates defects in gloves and can be found on the hands of the wearer.²⁵⁰ Moreover, if the gloved HCW has had hands-on contact with a patient colonized by MRSA or VRE, the process of removing the gloves will result in contamination of the hands of the HCW by these organisms up to one third of the time.

ANTIBIOTIC STEWARDSHIP

There is a world crisis in antibiotic resistance (see Fig. 50.2),^{251,252} which reflects in greatest measure the heavy use of systemic antibiotics worldwide over the past 30 years, especially in hospitals. Antimicrobial therapy has its greatest ecologic impact in the close confines of the ICU. Most nosocomial outbreaks caused by antibiotic-resistant microorganisms^{253,254} have occurred in patients hospitalized in an ICU. Antibiotic pressure, which promotes the exchange of genes encoding drug resistance by a variety of transfer mechanisms (Fig. 50.5),²⁵⁵ has been shown to be the single most important factor predisposing patients to nosocomial infection with resistant organisms. Modern-day ICUs are the breeding grounds for the multiply resistant bacteria that are now being encountered in hospitals throughout the world: MRSA; VRE; extended-spectrum β -lactamase-producing and carbapenemase-producing *K. pneumoniae* and *E. coli*, *Enterobacter*, *Serratia*, *Citrobacter*, and *P. aeruginosa* resistant to fluoroquinolones, aminoglycosides, or extended-spectrum β -lactams.^{47,58-61,251} Broad-spectrum antimicrobial therapy is the root cause of antibiotic-associated diarrhea and colitis caused by *C. difficile*.⁸³

Clearly, antimicrobials are widely overused and misused; more than 75% of patients in U.S. ICUs, other than coronary care units, receive antimicrobial agents, whereas studies indicate that more than half of hospitalized patients receiving antimicrobial therapy have no evidence of infection or clear justification to be receiving antibiotics.²⁵⁶ Moreover,

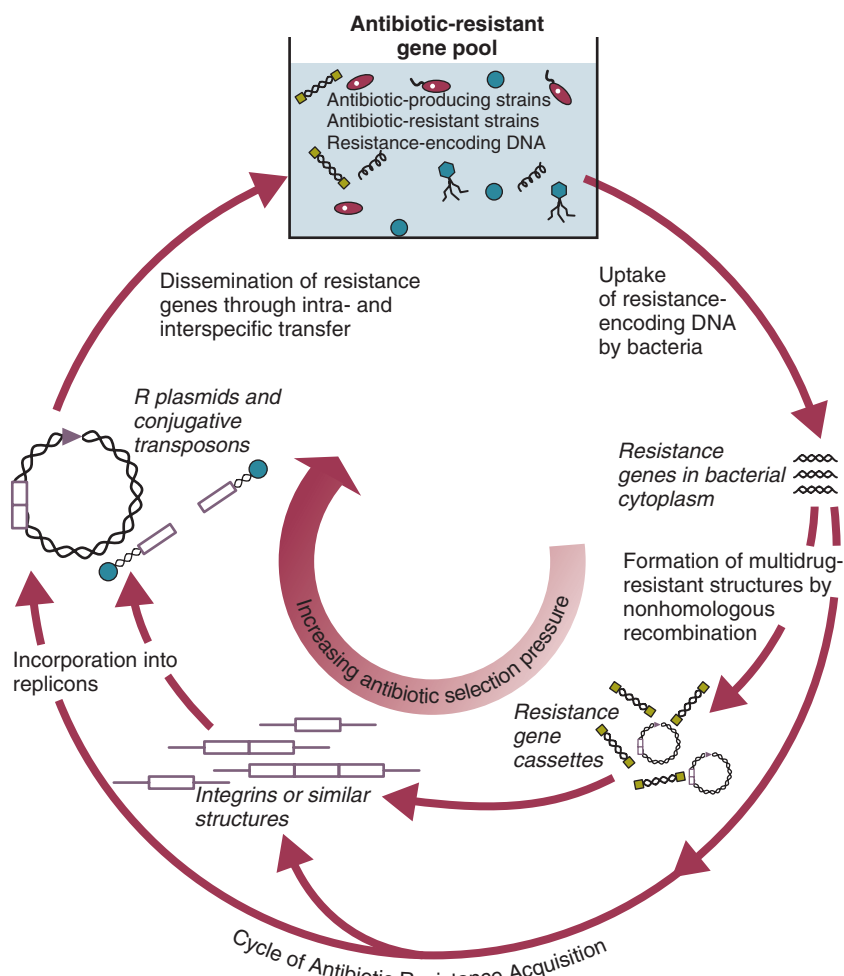

Figure 50.5 Schematic depicting the route by which antibiotic-resistant genes are acquired by bacteria in response to selection pressure of antibiotic use. The resistance gene pool represents all potential sources of DNA encoding antibiotic-resistant determinants in the environment; this includes hospitals, farms, or other microenvironments where antibiotics are used to control bacterial development. After uptake of single- or double-stranded DNA by the bacterial host, the incorporation of the resistance genes into stable replicons (DNA elements capable of autonomous replication) may occur by several different pathways that have not yet been identified. The involvement of integrins, as shown here, has been demonstrated for a large class of transposable elements in the *Enterobacteriaceae*. The resulting resistance plasmids could exist in linear or circular form in bacterial hosts. The final step in the cycle, dissemination, is brought about by one or more gene transfer mechanisms. (From Davies J: Inactivation of antibiotics and the dissemination of resistance genes. *Science* 1994;264:375-382.)

within ICUs, a high proportion of the antibiotics used are broad-spectrum/extended-spectrum penicillins, third- and fourth-generation cephalosporins, carbapenems, aminoglycosides, fluoroquinolones, or vancomycin. Greater efforts must be directed to improving the use of systemic antibiotics, especially within ICUs.

JCAHO now mandates that hospitals periodically review their use of antimicrobial agents through the use of antimicrobial audits.³⁰ Such audits should scrutinize the need for antimicrobial therapy—clear evidence of infection or clear justification for prophylactic use, the appropriateness of the regimen selected, and monitoring for therapeutic efficacy and side effects during therapy.²⁵⁷ Educational programs and institutional guidelines for antimicrobial use that permit the hospital staff to construct guidelines and policies based on local needs and judgments, aided by published

criteria, have been shown to materially improve antimicrobial use within the hospital.^{256,258} Other important methods for controlling antimicrobial use include a restricted formulary, the policies of the clinical microbiology laboratory on reporting of susceptibility testing, and automatic stop orders for surgical prophylaxis.²⁵⁶ Many institutions also place expensive or the most broad-spectrum drugs (e.g., third- and fourth-generation cephalosporins, extended-spectrum penicillins [e.g., piperacillin-tazobactam], carbapenems, aminoglycosides, fluoroquinolones, vancomycin, linezolid, fluconazole, echinocandins, lipid formulations of amphotericin B, ganciclovir, etc.) on a restricted list, requiring physicians who wish to use the agents to justify their use to a representative of the institutional antibiotic review committee.²⁵⁹ Such programs greatly reduce use of restricted antibiotics and are gaining ever-wider acceptance.

Excellent resources,²⁶⁰⁻²⁶² including other chapters in this book (Chapters 20, 51, 52), are available to guide the selection and use of anti-infective drugs in critically ill patients. However, several principles can reduce unnecessary antimicrobial therapy and improve the use of the drugs that are given:

1. Fever without other indications of infection should not mandate automatically beginning antimicrobial therapy in an ICU patient.
2. Unless antimicrobial therapy is being given for surgical prophylaxis, it is most likely being given for the treatment of suspected or proved infection. Gram-stained smears, cultures, and other appropriate diagnostic tests, as indicated, should be done without fail before beginning antimicrobial therapy for treatment of presumed infection in an ICU patient.
3. Whenever antimicrobial therapy is begun, the reason should be documented in the patient's record (e.g., "for the treatment of pneumonia," "for surgical prophylaxis").
4. When possible, a single drug and the most narrow-spectrum drug or drugs should be used, especially if the infecting organism or organisms are known at the outset.
5. The need for continued antimicrobial therapy should be reassessed daily. If cultures identify the infecting microorganism or microorganisms, therapy should be modified, aiming for the most narrow-spectrum drug or drugs likely to be effective. If diagnostic studies are negative after 48 to 72 hours and the patient is not exhibiting signs of sepsis, antibiotic therapy should be discontinued, unless the patient is profoundly granulocytopenic.
6. Beyond monitoring for efficacy and adverse drug effects such as hypersensitivity or organ toxicity, it is essential that monitoring include surveillance for superinfection by resistant bacteria or *Candida* and for *C. difficile* infection.
7. Surgical antimicrobial prophylaxis should not extend beyond 24 hours postoperatively^{263,264} and in most operations can be limited to a single dose.²⁶³

NOSOCOMIAL INFECTIONS AND SPECIFIC INFECTION CONTROL MEASURES

As noted earlier, most nosocomial infections, especially in immunologically competent patients and in ICUs, are causally related to surgical operations or exposure to invasive devices of various types (see [Tables 50.1](#) and [50.2](#)). Comprehensive guidelines for the prevention of infection with procedures or devices that pose the greatest risk (urinary catheters,^{133,134,265} endotracheal intubation and mechanical ventilatory support,¹³⁵ intravascular catheters and infusion therapy,¹³² hemodialysis,²⁶⁶ and surgery²⁶³) have been published and can form the basis for institutional policies and procedures. Health care professionals working in ICUs are obligated to be informed about prevention of infection associated with the procedures they perform and the devices with which they work daily.

INTRAVASCULAR DEVICE-RELATED BLOODSTREAM INFECTION

IMPACT

Obtaining and maintaining reliable vascular access has become one of the most essential features of modern-day intensive care. Unfortunately, vascular access is associated with substantial and generally underappreciated potential for producing iatrogenic disease, particularly bloodstream infection (BSI) originating from infection of the percutaneous intravascular device (IVD) used for vascular access (i.e., IVD-related BSI), often referred to as "line sepsis." Nearly 60% of all nosocomial bacteremias derive from vascular access in some form,¹⁸ and it is estimated that more than 500,000 IVD-related bloodstream infections occur in the United States each year.^{267,268} Early studies found that IVD-related BSIs are associated with excess attributable mortality rate ranging up to 35%²⁶⁹; however, subsequent case-control studies have not consistently found excess mortality rates, especially of this magnitude.²⁷⁰⁻²⁷² This controversy aside, all studies examining the impact of IVD-related BSI on patient outcomes have found that IVD-related BSIs are associated with increased length of hospitalization and excess health care costs, averaging \$30,000 per case.²⁶⁹⁻²⁷²

IVD-related BSIs are largely preventable. The goal must not be simply to identify and treat these infections but rather to prevent them. By drawing on existent knowledge of the pathogenesis and epidemiology of IVD-related BSI, rational and effective guidelines for prevention can be formulated.

DEFINITIONS

IVDs are associated with both local and systemic infection. The CDC has published definitions for IVD-related infection (see [Box 50.1](#)).^{16,17} These definitions are useful for the purposes of surveillance but rely heavily on the construct, central venous catheter-associated BSI, which implicitly assumes that each primary BSI (i.e., a BSI without an identifiable local infection) originates from a central venous catheter (CVC). This practice results in an overestimation of the true risk of CVC-related infection because not all primary BSIs originate from a central venous device; some are secondary BSIs deriving from unrecognized postoperative surgical site or intra-abdominal infections or nosocomial pneumonias or originate from other vascular devices such as peripheral venous catheters or arterial catheters used for hemodynamic monitoring.

By applying molecular subtyping techniques^{110,273,274} to the results of semiquantitative or quantitative cultures of the removed IVD and blood cultures or the results of cultures of blood drawn through the IVD and a separate concomitant percutaneous peripheral blood culture, it is now possible to reliably determine whether an IVD was the source of a nosocomial BSI. Using these new diagnostic techniques allows the formulation of simple but more rigorous definitions for IVD-related infection ([Table 50.6](#)), which we believe bear consideration as the standard for randomized trials and epidemiologic studies of IVD-related infection.¹⁸ Recently published guidelines have outlined clinical definitions of IVD-related BSI similar to those listed

Table 50.6 Proposed Definitions for Intravascular Device (IVD)-Related Colonization, Local Infection, and Bloodstream Infection (BSI) Based on Microbiologic Confirmation of the IVD as Source

IVD colonization	(i) A positive semiquantitative* (or quantitative [†]) culture of the implanted portion or portions of the IVD; (ii) absence of signs of local or systemic infection.
Local IVD infection	(i) A positive semiquantitative* (or quantitative [†]) culture of the removed IVD or a positive microscopic examination or culture of pus or thrombus from the cannulated vessel; (ii) clinical evidence of infection of the insertion site (i.e., erythema, induration, or purulence); but (iii) absence of systemic signs of infection and negative blood cultures, if done.
IVD-related BSI	<p><i>If the IVD is removed:</i></p> <p>(i) A positive semiquantitative* (or quantitative[†]) culture of the IVD or a positive culture of the catheter hub or infusate (or positive microscopic examination or culture of pus or thrombus from the cannulated vessel) AND one or more positive blood cultures, ideally percutaneously drawn, concordant for the same species, ideally by molecular subtyping methods; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.</p> <p><i>If the IVD is retained:</i></p> <p>(i) If quantitative blood cultures are available, cultures drawn both from the suspect IVD and a peripheral vein (or another IVD) are both positive and show a marked step up in quantitative positivity (fivefold or greater) in the IVD-drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.</p> <p>OR</p> <p>(i) If automated monitoring of incubating blood cultures is available, blood cultures drawn concomitantly from the suspect IVD and a peripheral vein (or another IVD) show both are positive, but the IVD-drawn blood culture turns positive more than 2 hours before the peripherally drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.</p>

*Roll plate of cannula segment(s) >15 colony-forming units (CFUs).

[†]Sonication culture of cannula segment(s) ≥10³ CFUs/mL.

Table 50.7 Clinical, Epidemiologic, and Microbiologic Features of Intravascular Device-Related Bloodstream Infection

Nonspecific	Suggestive of Device-Related Etiology
Fever	Patient unlikely candidate for sepsis (e.g., young, no underlying diseases)
Chills, shaking rigors*	Source of sepsis inapparent, no identifiable local infection
Hypotension, shock*	Intravascular device in place, especially central venous catheter
Hyperventilation, respiratory failure	Inflammation or purulence at insertion site
Gastrointestinal*	Abrupt onset, associated with shock
Abdominal pain	Bloodstream infection caused by staphylococci (especially coagulase-negative staphylococci), <i>Corynebacterium</i> , <i>Candida</i> , <i>Trichophyton</i> , <i>Fusarium</i> , or <i>Malassezia</i> species [†]
Vomiting	
Diarrhea	
Neurologic*	Very high-grade (>25 CFUs/mL) candidemia
Confusion	Cluster of cryptogenic infusion-associated bloodstream infections caused by <i>Enterobacter cloacae</i> , <i>Pantoea agglomerans</i> , or <i>Serratia marcescens</i> * [†]
Seizures	Sepsis refractory to antimicrobial therapy or dramatic improvement with removal of cannula and infusion*

*Commonly seen in overwhelming gram-negative sepsis originating from contaminated infusate, peripheral suppurative phlebitis, or septic thrombosis of a central vein.

[†]Conversely, bacteremia caused by streptococci, aerobic gram-negative bacilli, or anaerobes is unlikely to derive from an intravascular device.

Modified from Maki DG, Mermel LA: Infections due to infusion therapy. In Bennett JV, Brachman PS (eds): *Hospital Infections*, 4th ed. Boston, Lippincott-Raven, 1998.

in Table 50.7, although molecular subtyping methods are not recommended for routine clinical diagnosis of IVD-related BSI.²⁷⁵

RECOGNITION AND DIAGNOSIS

Clinical Features

Recent evidence-based guidelines provide the best current information on the evaluation of the ICU patient with fever or other signs of sepsis.³⁴ Before any decision regarding initiation of antimicrobial therapy or removal of an IVD, the patient must be thoroughly examined to identify all plausible sites of infection including VAP, catheter-associated urinary tract infection, surgical site infection, IVD-related BSI, *C. difficile* infection, and other infections.³⁴

Despite the challenge of identifying the source of a patient's signs of sepsis,³⁴ several clinical, epidemiologic,

and microbiologic findings point strongly toward an IVD as the source of a septic episode (Table 50.7).²⁶⁷ Patients with an abrupt onset of signs and symptoms of sepsis without any identifiable local infection such as pneumonia or surgical site infection should prompt suspicion of infection of an IVD. The presence of inflammation or purulence at the catheter insertion site is now uncommon in patients with IVD-related BSI.²⁷⁶ However, if inflammation, especially any purulence, is seen in combination with signs and symptoms of sepsis, it is highly likely the patient has IVD-related BSI and should prompt removal of the device. Finally, recovery of certain microorganisms in multiple blood cultures, such as staphylococci, *Corynebacterium* or *Bacillus* species, or *Candida* or *Malassezia*, strongly suggests infection of an IVD.

Blood Cultures

Starting anti-infective drugs for suspected or presumed infection in the critically ill patient without first obtaining blood cultures from two separate sites, at least one of which is drawn from a peripheral vein by percutaneous venipuncture, is indefensible. The volume of blood cultured is essential to maximize the sensitivity of blood cultures for diagnosis of bacteremia or candidemia: in adults, obtaining at least 20 mL, ideally 30 mL, per drawing (each specimen, containing 10 mL or 15 mL, inoculated into aerobic and anaerobic media) significantly improves the yield as compared with obtaining only 5 mL at each drawing and culturing a smaller total volume.^{277,278} In adults, if at least 30 mL of blood is cultured, 99% of detectable bacteremias should be identified.^{277,279} Similar operating characteristics are achieved in the pediatric population using a weight-based graduated volume approach to blood cultures.²⁸⁰ Standard blood cultures drawn through CVCs provide excellent sensitivity for diagnosis of BSI but are less specific than cultures obtained from a peripheral vein.^{281,282} If the patient has a long-term multilumen catheter, it may be reasonable to obtain a specimen from each lumen of the catheter because studies have found discordance ($\approx 30\%$) among cultures obtained from different lumens of the same catheter.²⁸³

Every effort must be made to prevent introduced contamination when drawing blood cultures because a single contaminated blood culture has been shown to prolong hospitalization by 4 days and increase the costs of hospitalization by \$4100 to \$4400.^{284,285} Tincture of iodine, isopropyl alcohol, chlorhexidine, or povidone-iodine combined with alcohol rather than povidone-iodine alone should be used for skin antisepsis prior to venipuncture for blood cultures, recognizing that studies have shown significantly reduced rates of contamination with use of these agents.^{204,285,286} Up to 30% of blood cultures positive for coagulase-negative staphylococcus represent true infection^{287,288}; however, the majority of single positive cultures represent contamination,²⁸⁸ a finding that should reemphasize the need to obtain cultures from *two* separate sites whenever BSI is suspected.

Cultures of Removed Intravascular Devices

Removal and direct culture of the IVD has historically been the gold standard for confirming the presence of IVD-related BSI, particularly with short-term IVDs. Studies have shown that culturing catheter segments semiquantitatively

on solid media²⁸⁹ or quantitatively in liquid media (e.g., removing the adherent organisms by sonication²⁹⁰) provides superior sensitivity and specificity for diagnosis of IVD-related BSI, with a strong correlation between high colony counts and line sepsis. Growth of greater than or equal to 15 CFUs from a catheter segment by semiquantitative culture or growth of greater than or equal to 10^3 CFUs from a catheter cultured after sonication with accompanying local inflammation or signs of sepsis indicates local catheter infection. Significant growth in the absence of local or systemic inflammation suggests colonization of the device; if continued vascular access is necessary, a new device should be placed in a new location rather than replacing it with a new one in the same location by guidewire exchange.

Although recent studies²⁹¹ have suggested that quantitative methods (e.g., sonication) are superior to the semiquantitative methods (e.g., roll plate), other studies have shown them to be equivalent.^{292,293} Because hub contamination progressing to intraluminal colonization is the primary route of infection for long-term devices (e.g., devices in place >10 days), quantitative techniques may be superior to semiquantitative techniques in detecting infections from these types of devices because they remove organisms from both the internal and external surface of catheters.²⁹³ In contrast, semiquantitative methods may be preferred over quantitative methods in cases of suspected infection related to a short-term device (e.g., devices in place <10 days) because the primary route of infection in this setting is caused by extraluminal ingress of skin organisms at the catheter insertion site and the semiquantitative method is simple, less expensive, and allows identification of the infecting organisms a day earlier.

Direct and impression Gram stains²⁹⁴ or acridine orange stains²⁹⁵ of intravascular segments of removed catheters have shown excellent correlation with quantitative techniques for culturing catheters and can permit rapid diagnosis of catheter-related infection.

To rigorously identify the mechanism of IVD-related BSI in prospective studies, it is necessary to culture all potential sources of microorganisms at the time of catheter removal (Fig. 50.6): skin of the insertion site, each catheter hub, infusate from each lumen, as well as implanted catheter segments. If the results of these cultures appear to link a BSI with microorganisms isolated from one or more portions of the device by phenotypic criteria, efforts then need to be made to conclusively establish concordance, beyond speciation and antimicrobial susceptibility pattern, using one or more molecular subtyping systems such as multilocus enzyme electrophoresis, plasmid profile, or restriction-enzyme digestion of genomic DNA analyzed by pulsed-field electrophoresis.^{273,274,278,295}

Diagnosis of Infection with Implanted Long-Term Intravascular Devices

The methods described earlier require removal of the device for confirmation of IVD-related BSI. This can pose formidable challenges to management with long-term, surgically implanted IVDs such as Hickman and Broviac catheters, cuffed and tunneled hemodialysis catheters, and subcutaneous central venous ports. Only 15% to 45% of

Figure 50.6 Potential sources of infection of a percutaneous intravascular device (IVD): the contiguous skin flora, contamination of the catheter hub and lumen, contamination of infusate, and hematogenous colonization of the IVD from distant, unrelated sites of infection. HCW, health care worker. (From Crnich CJ, Maki DG: The promise of novel technology for the prevention of intravascular device-related bloodstream infection. I. Pathogenesis and short-term devices. Clin Infect Dis 2002;34:1232-1242.)

long-term IVDs that are removed for suspected infection are truly colonized or infected at the time of removal.²⁹⁶⁻²⁹⁹ To avoid unnecessary removal of IVDs, methods have been developed to diagnose IVD-related BSI while allowing the device to remain in place: (1) paired quantitative blood cultures drawn from the IVD and percutaneously from a peripheral vein²⁹³ and (2) differential time to positivity (DTP) of paired standard blood cultures, one drawn from the IVD and the other from a peripheral vein.³⁰⁰

If a laboratory has available an automated quantitative system for culturing blood (e.g., Isolator lysis centrifugation system, Wampole Laboratories, Cranbury, NJ), quantitative blood cultures drawn through the IVD and concomitantly by venipuncture from a peripheral vein (or another IVD) can permit the diagnosis of IVD-related bacteremia or fungemia to be made with sensitivity and specificity in the range of 80% to 95%,²⁹³ without removal of the catheter, if empiric antimicrobial therapy has not yet been initiated. IVD-drawn cultures demonstrating 5- to 10-fold higher concentrations of microorganisms per milliliter, as compared with counts of the same microorganism obtained in a culture drawn from a peripheral vein, confirm the presence of IVD-related BSI.

The differential-time-to-positivity (DTP) of paired blood cultures, one drawn through the IVD and the second, concomitantly from a peripheral vein, has also been shown to reliably identify IVD-related BSI of long-term IVDs if the blood culture drawn from the IVD turns positive 2 or more hours before the culture drawn peripherally. In studies of patients with long-term IVDs, the sensitivity and specificity of DTP ranged from 82% to 94% and 88% to 91%, respectively.^{293,300} The performance of DTP in short-term IVDs has recently been examined, with disappointing results,³⁰¹ a finding that is not entirely unexpected given the predominant extraluminal route of infection with these devices.

Detection of Contaminated Infusate

To diagnose infection caused by contaminated infusate, a sample of IV fluid, aspirated from the line, should be cultured quantitatively and qualitatively²⁸⁹; concordance with positive peripheral blood cultures, without another identifiable source for the patient's BSI, definitively implicates infected infusate as the cause of the BSI. Anaerobic culture techniques are not necessary unless blood or another biological product is involved.

INCIDENCE

Prospective studies, in which every attempt was made to conclusively identify the presence of an IVD-related BSI, show that every type of IVD carries some risk of causing BSI; however, the magnitude of risk varies greatly, depending on the type of device (Table 50.8).³⁰² The device that poses the greatest risk of IVD-related BSI today is the CVC in its many forms (see Table 50.8): short-term, noncuffed, single-lumen or multilumen catheters inserted percutaneously into the subclavian or internal jugular vein have shown rates of catheter-related BSI in the range of 3% to 5% (2 to 3 per 1000 IVD-days).³⁰² Far lower rates of infection have been encountered with surgically implanted cuffed Hickman or Broviac catheters and subcutaneous central venous ports (1 and 0.2 per 1000 IVD-days, respectively).³⁰² Contrary to popular belief, peripherally inserted central catheters (PICCs) used in inpatients and arterial catheters are associated with rates of catheter-related BSI approaching those seen with short-term, noncuffed, and nontunneled, multilumen CVCs—up to 2.1³⁰³ and 3.4³⁰⁴ BSIs per 1000 IVD-days, respectively.

PATHOGENESIS AND RISK FACTORS

Two major sources of IVD-related BSI exist: (1) colonization of the IVD, *catheter-related infection*, and (2) contamination of the fluid administered through the device, *infusate-related infection*.²⁶⁷ Contaminated infusate is the cause of most *epidemic* IVD-related BSIs; in contrast, catheter-related infections are responsible for most *endemic* IVD-related BSIs.¹⁸

In order for microorganisms to cause catheter-related infection, they must first gain access to the extraluminal or intraluminal surface of the device, where they can adhere and become incorporated into a biofilm that allows sustained infection and hematogenous dissemination.³⁰⁵ Microorganisms gain access to the bloodstream by one of three mechanisms (see Fig. 50.7): (1) skin organisms invade the percutaneous tract, probably assisted by capillary action, at the time of insertion or in the days following; (2) microorganisms contaminate the catheter hub (and lumen) when the catheter is inserted over a percutaneous guidewire or later manipulated; or (3) organisms are carried hematogenously to the implanted IVD from remote sources of local infection such as pneumonia.

With short-term IVDs (e.g., in place <10 days) such as peripheral IV catheters; arterial catheters; and noncuffed, nontunneled CVCs, most device-related BSIs are of cutaneous origin, from the insertion site, and gain access extraluminally, occasionally intraluminally at insertion with the guidewire.^{306,307} In contrast, contamination of the catheter hub and luminal fluid is the predominant mode of invasive

Table 50.8 Rates of Intravascular Device (IVD)-Related Bloodstream Infection (BSI) Caused by Various Types of Devices Used for Vascular Access in Adults

Device	Studies, <i>n</i>	Catheters, <i>n</i>	IVD-days, <i>n</i>	BSIs, <i>n</i>	Rates of IVD-Related BSI			
					Per 100 Devices		Per 1000 IVD-days	
					Pooled Mean	95% CI	Pooled Mean	95% CI

infection with *long-term* IVDs (e.g., in place >10 days) such as cuffed Hickman- and Broviac-type catheters, subcutaneous central ports, and PICCs.^{308,309}

Also important is recognizing that infusate (parenteral fluid, blood products, or IV medications) administered through an IVD can also occasionally become contaminated and produce device-related BSI. Contaminated fluid is fortunately an infrequent cause of endemic infusion-related infection with most short-term IVDs; it is, however, an important cause of BSIs with arterial catheters used for hemodynamic monitoring and long-term IVDs such as Hickman or Broviac catheters, cuffed hemodialysis CVCs, and subcutaneous central venous ports.^{307,310,311}

Most nosocomial epidemics of infusion-related BSI have been traced to contamination of infusate by gram-negative bacilli, introduced during its manufacture (intrinsic contamination) or during its preparation and administration in the hospital (extrinsic contamination).^{146,312} If an epidemic is suspected, the epidemiologic approach must be methodical and thorough yet expeditious, directed toward establishing the bona fide nature of the putative epidemic infections (i.e., ruling out “pseudoinfections”)²⁴⁶ and confirming the existence of an epidemic; defining the reservoirs and modes of transmission of the epidemic pathogens; and most importantly, controlling the epidemic quickly and completely. Control measures are predicated on accurate delineation of the epidemiology of the epidemic pathogen. The essential steps in dealing with a suspected

nosocomial outbreak have recently been reviewed (and are discussed later).²⁶⁷

In recent years the factors associated with an increased risk of IVD-related BSI have become better delineated (Table 50.9). Prolonged hospitalization and severity of illness clearly influence the risk, and clinical states such as granulocytopenia, AIDS, and bone marrow transplantation have been associated with fourfold to sixfold increased rates of IVD-related BSI.^{313,314} However, the features of the IVD, its insertion, and its maintenance appear to have far greater impact on the overall risk of infection. In 289 patients, Merrer and colleagues³¹⁵ found that insertion of an IVD in the femoral versus the subclavian vein was associated with a greatly increased risk of infection (20 versus 3.7 BSIs per 1000 IVD-days, $p < 0.001$) and thrombotic complications (21.5% versus 1.9%, $p < 0.001$).³¹⁵ Moreover, Robert and colleagues³¹⁶ found that patients with primary BSI were more likely to have received care during times when there was a lower nursing-to-patient ratio and a higher proportion of temporary (“float”) nurses rather than the full-time nursing staff.³¹⁶

MICROBIOLOGY

Figure 50.7 summarizes the microbial profile of IVD-related BSI from 159 published prospective studies.³¹⁷ As might be expected from knowledge of the pathogenesis of these infections, skin microorganisms account for the largest proportion of these infections.

Table 50.9 Risk Factors for Intravascular Device–Related Bloodstream Infection with Short-Term Use

Risk Factor (with No. of Studies)	Relative Risk or Odds Ratio
Underlying Disease	
AIDS (2)	4.8
Neutropenia (2)	1-15.1
Gastrointestinal disease (1)	2.4
Surgical service (1)	4.4
ICU/CCU placement (3)	0.4-6.7
Extended hospitalization (3)	1-6.7
Other intravascular devices (2)	1-3.8
Systemic antibiotics (3)	0.1-0.5
Active infection at another site (2)	8.7-9.2
High APACHE III score (1)	4.2
Mechanical ventilation (1)	2-2.5
Transplant recipient (1)	2.6
Features of Insertion	
Difficult insertion (1)	5.4
Maximal sterile barriers (1)	0.2
Tunneling (2)	0.3-1
Insertion over a guidewire (8)	1-3.3
Insertion Site	
Internal jugular vein (6)	1-3.3
Subclavian vein (5)	0.4-1
Femoral vein (2)	3.3-4.8
Defatting insertion site (1)	1.0
Use of a multilumen catheter (8)	–6.5
Catheter Management	
Routine change of IV set (2)	1.0
Staffing in SICU (nurse-to-patient ratio) (1)	
1:2	61.5
1:1.5	15.6
1:1.28	4.0
1:1	1.0
Inappropriate catheter usage (1)	5.3
Duration of catheterization >7 days (5)	1-8.7
Colonization of catheter hub (3)	17.9-44.1
Parenteral nutrition (2)	–4.8

Modified from Safdar NS, Kluger DM, Maki DG: A review of risk factors for catheter-related infection caused by percutaneously inserted, noncuffed central venous catheters: Implications for preventive strategies. *Medicine* 2002;81:466-479.

summarizes the recommendations of the 2011 HICPAC guideline for the prevention of IVD-related BSI and scores each recommendation on the basis of the quality of the available scientific evidence. It must be reaffirmed that measures for prevention of any nosocomial infection must, wherever possible, be based on the best understanding of pathophysiology and epidemiology and, whenever possible, controlled clinical trials.

At-Device Insertion

1. *Choice of catheter and site of device insertion:* Obviously, the choice of IVD inserted into a patient will be guided primarily by that patient's particular needs (e.g., hemodialysis versus fluid administration). However, the astute clinician can mitigate much of the risk associated with vascular access by choosing the best device for the task at hand and inserting the IVD in a location associated with the least risk of infection. Studies suggest that multilumen IVDs are associated with a higher risk of infection than single-lumen catheters.³¹⁸ That said, if a patient has need for multiple infusions, inserting several single-lumen catheters will pose greater risks than a single multilumen catheter.

To date, there have been no randomized studies designed to evaluate the optimal location for placement of short-term CVCs. However, the data accumulated from numerous observational studies suggest that the lowest risk of IVD-related BSI is seen with subclavian vein insertion and the highest risk with femoral vein insertion, with an intermediate level of risk associated with jugular vein insertions.^{307,315}

The femoral vein is often used for central venous access, especially on nonsurgical services, because of the ease of cannulation and the lower risk of mechanical complications from insertion (i.e., bleeding or pneumothorax). Unfortunately, prospective studies evaluating the risk of femoral vein device placement have shown that CVCs placed in the femoral vein are more likely to be colonized at the time of removal than catheters placed in the internal jugular vein (RR = 4.7, CI = 2 to 8.8, $p = 0.0001$)³¹⁹ and are associated with an increased risk of IVD-related BSI when compared with CVCs placed in the subclavian vein (4.4% versus 1.5%, $p = 0.07$).³¹⁵ Furthermore, prospective studies have found higher rates of catheter-related deep vein thrombosis with femoral catheters, in the range of 7% to 25%.^{314,315} In general, we believe femoral access should be used only if emergent access is required, the inexperience of the operator limits placement in the upper body, or there is a contraindication to placement in the upper body (no available sites, an extensive burn, or severe coagulopathy). If a short-term CVC must be placed in the femoral vein or artery, we believe it is important that the catheter insertion site be located at least 2 inches (5 cm) below the inguinal crease or an intertriginous area, which is heavily colonized with bowel organisms and yeasts; this also allows a more secure protective dressing to be affixed.

In contrast to short-term CVCs, observational studies of hemodialysis catheters have not been able to confirm a lower rate of infection with catheters inserted in the subclavian vein as compared with those inserted in the internal jugular vein,³²⁰ although there is still excess risk

TREATMENT

Treatment of IVD-related BSI is discussed in Chapter 54 (Specific Infections with Critical Care Implications), under “Device-Related Endovascular Infections.”

STRATEGIES FOR PREVENTION

Recommendations for the prevention of IVD-related BSIs were recently published by the Hospital Infection Control Practices Advisory Committee (HICPAC).¹³² **Table 50.10**

Figure 50.7 Microbial profile of intravascular device-related bloodstream infection based on an analysis of 159 published prospective studies. (Modified from Maki DG, Kluger DM, Crnich CJ: The microbiology of intravascular device-related (IVDR) infection in adults: An analysis of 159 prospective studies and implications for prevention and treatment. In Abstracts and Proceedings from the 40th Annual Meeting of the Infectious Disease Society of America. Chicago, Infectious Disease Society of America, 2002.)

Table 50.10 Summary of CDC/HICPAC Guideline Recommendations for Prevention of Intravascular Device (IVD)-Related Bloodstream Infection (BSI) in Adults

Recommendation	Strength*	Recommendation	Strength*
General Measures			
• Educate health care personnel regarding indications for IVD use, proper procedures for IVD insertion/maintenance, and infection control measures. Periodically assess knowledge of and adherence to guidelines. Designate only trained personnel who demonstrate competence in IVD insertion/maintenance.	IA	• Weigh risks against benefits of placing CVC at recommended site to reduce infectious complications versus risk for mechanical complications (e.g., pneumothorax).	IA
• Ensure adequate nursing staffing levels in ICUs.	IB	• Use radial, brachial, or dorsalis pedis sites for peripheral arterial catheters, rather than femoral or axillary.	IB
• Use “bundles,” whereby multifaceted strategies are bundled together to improve compliance with evidence-based recommended practices.	IB	• Prepare clean skin with >0.5% chlorhexidine preparation with alcohol before insertion of CVCs and peripheral arterial catheters and during dressing changes; can use tincture of iodine, an iodophor, or 70% alcohol, in patients with a contraindication to use of chlorhexidine.	IA
Hand Hygiene, Aseptic Technique, and Maximal Sterile Barrier Precautions		• Use sutureless securement device to reduce risk of infection.	II
• Perform hand hygiene and maintain aseptic technique, before and after inserting, replacing, accessing, repairing, or dressing an IVD.	IB	• Use sterile sleeve to protect pulmonary artery catheters during insertion.	IB
• Use maximal sterile barrier precautions during insertion of CVCs, PICCs, or guidewire exchange: mask, cap, sterile gown, sterile gloves, sterile full-body drape.	IB	• Use either sterile gauze or sterile, transparent, semipermeable dressing to cover catheter site.	IA
• Use minimum of cap, mask, sterile gloves, and small sterile fenestrated drape during insertion of peripheral arterial catheters.	IB	IVD Maintenance	
• Use maximal sterile barrier precautions during insertion of axillary or femoral artery catheters.	II	• Promptly remove any IVD that is no longer essential.	IA
• Don new sterile gloves before handling new catheter during guidewire exchange.	II	• Replace gauze dressings on short-term CVC sites every 2 days.	II
Use either clean or sterile gloves when changing the dressing on IVDs.	IC	• Replace transparent dressings on short-term CVC sites at least every 7 days.	IB
IVD Insertion		• Replace dressing if it becomes damp, loosened, or visibly soiled.	IB
• Use subclavian site for nontunneled CVC placement, rather than jugular or femoral (IB) (except avoid subclavian site for patients on dialysis or with advanced kidney disease—IA).	See text	• Monitor IVD insertion site when changing dressing or by palpation through intact dressing on regular basis; dressing should be removed to examine site if local or systemic signs of infection are present.	IB
• Avoid femoral vein for central venous access.	IA	• Do not use systemic antibiotic prophylaxis; and do not use topical antibiotic ointments on IVD exit sites, except for dialysis catheters.	IB
		• Use a 2% chlorhexidine wash for daily skin cleansing.	II

Table 50.10 Summary of CDC/HICPAC Guideline Recommendations for Prevention of Intravascular Device (IVD)-Related Bloodstream Infection (BSI) in Adults (Continued)

Recommendation	Strength*	Recommendation	Strength*
<ul style="list-style-type: none"> Replace administration sets in continuous use no more frequently than at 96-hour intervals but at least every 7 days (IA). When blood, blood products, or fat emulsions are given, replace tubing within 24 hours of initiating the infusion (IB). With propofol infusions, replace tubing every 6 or 12 hours, when the vial is changed (IA). 	See text	<ul style="list-style-type: none"> Do not use guidewire exchanges to replace a non-tunneled catheter suspected of infection; a new device should be placed in a new location. 	IB
<ul style="list-style-type: none"> Change needleless IV catheter system components at least as frequently as the administration set, but no more frequently than every 72 hours (for needleless connectors, do not change more frequently than every 72 hours or according to manufacturers' recommendations). 	II	<ul style="list-style-type: none"> When adherence to aseptic technique cannot be ensured (e.g., with insertion of catheter during a medical emergency), replace the catheter as soon as possible (i.e., within 48 hours). 	IB
<ul style="list-style-type: none"> Minimize contamination of needleless IV catheter systems by scrubbing the access port with an appropriate antiseptic (chlorhexidine, povidone-iodine, an iodophor, or 70% alcohol) and accessing the port only with sterile devices. 	IA	<p>Technology</p> <ul style="list-style-type: none"> Use chlorhexidine–silver sulfadiazine or minocycline–rifampin–impregnated CVC in patients whose catheter is expected to remain in place >5 days, if the rate of IVD-related BSI is not decreasing after successful implementation of a comprehensive strategy to reduce rates of such infections. 	IA
<ul style="list-style-type: none"> Replace peripheral IV lines every 72–96 hours. 	IB	<ul style="list-style-type: none"> Use chlorhexidine-impregnated sponge dressing for temporary short-term catheters if the IVD-related BSI rate is not decreasing despite adherence to basic prevention measures. 	IB
<ul style="list-style-type: none"> Do not routinely replace CVCs, PICCs, hemodialysis catheters, pulmonary artery catheters (IB), or arterial catheters (II), solely for prevention of infection. 	See text	<ul style="list-style-type: none"> Use prophylactic antibiotic lock solution <i>only</i> in patients with long-term IVDs who have continued to experience IVD-related BSIs despite consistent application of infection control practices. 	II
<ul style="list-style-type: none"> Do not remove CVCs or PICCs solely because of fever unless IVD infection is suspected, but replace catheter if purulence is seen at the exit site, especially if the patient is hemodynamically unstable and IVD-related BSI is suspected. 	II		

CVC, central venous catheter; ICU, intensive care unit; IV, intravenous; PICC, peripherally inserted central venous catheter.

Data from O'Grady NP, Alexander M, Burns LA, et al: Healthcare Infection Control Practices Advisory Committee (HICPAC). Guidelines for the prevention of intravascular catheter-related infections. Clin Infect Dis 2011;52(9):e162-93.

*Taken from CDC/HICPAC system of weighting recommendations based on scientific evidence: IA, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. IB, strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale; or an accepted practice (e.g., aseptic technique) supported by limited evidence. IC, required by state or federal regulations, rules, or standards. II, suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale.

associated with femoral vein placement.³²¹ More importantly, prospective studies of catheters used for hemodialysis have demonstrated a significant risk of great vein thrombosis and stenosis in catheters inserted into the subclavian vein that approaches 40% to 50% as compared with rates of 0% to 10% with catheters inserted into the internal jugular vein.^{322,323} On the basis of these data, internal jugular vein insertion is preferable to subclavian vein insertion for central access for hemodialysis.

2. **Barrier precautions:** Hand hygiene with an antiseptic-containing preparation, either conventional handwashing with chlorhexidine (2% to 4%) or with a waterless alcohol rub or gel,¹⁷⁴ must always precede the insertion of an IVD and should also precede subsequent handling of the device or its administration set.¹³² A new pair of

disposable, nonsterile gloves, using a “no-touch” technique, is adequate for the placement of peripheral IV catheters in most patients; however, sterile gloves should be used during insertion in high-risk patients such as those with granulocytopenia. Sterile gloves are strongly recommended for placement of all other types of IVDs that are associated with a 1% or higher risk of associated bacteremia, specifically arterial catheters and all types of centrally placed devices including PICCs.¹³²

Studies have shown that the use of maximal barriers including a long-sleeved, sterile surgical gown, mask, cap and large sterile drape, and sterile gloves significantly reduces the risk of CVC-related BSI (0.08 BSIs with maximal barriers versus 0.5 BSIs per 1000 IVD-days without maximal barriers, $p = 0.02$).³²⁴ The use of maximal barriers has further been shown to be highly

- cost effective.³²⁴ Considering that of all IVDs, CVCs are most likely to produce nosocomial BSI, a strong case can be made for mandating maximal barrier precautions during the insertion of all central IVDs.¹³² They are not necessary, however, for arterial catheters used for hemodynamic monitoring, during which sterile gloves and a sterile fenestrated drape will suffice, because using maximal sterile barrier precautions does not appear to reduce the risk of arterial catheter-related BSI.³²⁵ However, recently published guidelines for the prevention of IVD-related BSI¹³² recommend that in addition to using a minimum of a cap, mask, sterile gloves, and a small sterile fenestrated drape during the insertion of all peripheral arterial catheters, maximal sterile barrier precautions be used for axillary and femoral artery catheter insertion (see Table 50.10), although the evidence to support this recommendation is not strong.³²⁶
3. *IV teams:* Good technique is also essential. Studies have shown that the use of special IV therapy teams, consisting of trained nurses or technicians who can assure a consistent and high level of aseptic technique during catheter insertion and in follow-up care of the catheter, have been associated with substantially lower rates of catheter-related BSI and are cost effective.^{327,328} But even if an institution does not have an IV team, it can greatly reduce its rate of IVD-related BSI by formal education of nurses and physicians and stringent adherence to IVD care protocols.^{329,330}
 4. *Cutaneous antisepsis:* Given the evidence for the importance of cutaneous microorganisms in the pathogenesis of short-term IVD-related infections, measures to reduce colonization of the insertion site would seem of the highest priority, particularly the choice of chemical antiseptics for disinfection of the site. Nine randomized, prospective trials comparing a chlorhexidine-containing antiseptic to either povidone-iodine or alcohol for preparation of the skin prior to insertion of a short-term IVD have been reported.^{205-207,331} In the largest study to date, a randomized trial in 1050 CVCs and arterial catheters placed in a university hospital ICU, cutaneous antisepsis with 1% tincture of chlorhexidine showed a highly significant reduction in IVD-related BSIs compared with an iodophor (RR = 0.35, $p < 0.01$).³³¹ More recently, a meta-analysis that examined results from eight of the nine aforementioned studies found that use of chlorhexidine was associated with a nearly 50% reduction in the risk of IVD-related compared with povidone-iodine (RR = 0.49, 95% CI = 0.28 to 0.88).²⁰⁵

Insertion Site Care and IVD Maintenance

1. *IVD dressings:* IVDs can be dressed with sterile gauze and tape or with a sterile transparent, semipermeable, polyurethane film dressing. The available data suggest that the two types of dressings are equivalent in terms of their impact on IVD-related BSI with peripheral IVs and short-term CVCs.³³²⁻³³⁴ In contrast, results from studies of arterial catheters have found that polyurethane dressings greatly increase the risk of IVD-related BSI.^{332,335} As a result, polyurethane dressings should probably not be used on arterial catheters until future studies confirm their safety.
2. *Topical antimicrobial ointments:* In theory, application of a topical antimicrobial agent to the catheter insertion site should confer some protection against microbial invasion. Clinical trials of a topical combination antibacterial ointment containing polymyxin, neomycin, and bacitracin with peripheral IVs have shown marginal benefit,³³⁶ but the use of polyantibiotic ointments has been associated with a fivefold increased frequency of *Candida* infection, limiting their utility.^{336,337} One recent double-blind, placebo-controlled, randomized clinical trial in hemodialysis patients with permanent tunneled cuffed dialysis catheters showed that the use of topical bacitracin, gramicidin, and polymyxin B at the catheter exit site as compared with topical placebo was associated with a reduction in catheter-related bacteremia (0.63 versus 2.48 per 1000 IVD-days, $p = 0.0004$) and mortality rate (3 versus 13 deaths, $p = 0.004$), without an increase in *Candida* infection.³³⁸
The topical antibacterial mupirocin, which is active primarily against gram-positive organisms, was shown in one study to significantly reduce colonization of internal jugular catheters without increasing colonization by *Candida* spp.,³³⁹ and a study by Sesso and colleagues³⁴⁰ showed significant reductions in hemodialysis catheter colonization (3.17 versus 14.27 per 1000 IVD-days, $p \leq 0.001$) and *S. aureus* IVD-related BSIs (0.71 versus 8.92 BSIs per 1000 IVD-days, $p \leq 0.001$).³⁴⁰ Unfortunately, resistance of *S. aureus*³⁴¹ and coagulase-negative staphylococci³⁴² rapidly emerges during wide-scale mupirocin use,³⁴³ which contravenes its use as a topical agent for the prevention of IVD-related BSI at this time.¹³²
Three prospective studies of topical povidone-iodine ointment applied to central venous catheter sites have failed to show a statistical benefit to its use,^{336,344,345} but a single comparative trial in subclavian hemodialysis catheters showed that the use of topical povidone-iodine ointment was associated with a fourfold reduction in the incidence of IVD-related *S. aureus* BSI.³⁴⁶
Based on these data, if a topical agent is to be used with hemodialysis catheters, either an iodophor or topical bacitracin, gramicidin, and polymyxin B (not currently available in the United States) may be most desirable.¹³²
3. *Replacement of the device:* Studies have shown that peripheral IVs may be safely left in place for up to 96 hours if the patient and the insertion site are monitored closely.³⁴⁷ Studies have suggested that the duration of peripheral catheterization may be prolonged even further,³⁴⁸ but viewing reports of increasing nosocomial *S. aureus* bacteremias linked to prolonged peripheral venous catheterization,³⁴⁹ more studies are required before this can become considered acceptable routinely.
Scheduled replacement of short-term, noncuffed, nontunneled CVCs has long been practiced in many centers; however, some studies have called this practice into question.³⁵⁰ Moreover, a meta-analysis found no benefit to routine replacement of short-term CVCs.³⁵¹ On the basis of these data, there appears to be no indication for scheduled replacement of short-term CVCs that are functioning well and show no clinical signs of infection.
4. *Guidewire exchanges of CVCs:* The management of CVCs that must be replaced, either because of mechanical

malfunction or suspected infection, deserves special attention. Replacement of CVCs by guidewire exchange is associated with a reduced risk of mechanical complications^{350,351}; however, it is also associated with an increased risk of the newly placed CVC becoming infected and causing CVC-related BSI.³⁵⁰ As a result, if circumstances necessitate guidewire exchange for placement of a new catheter (e.g., the patient has limited sites for access, is morbidly obese, or is at high risk of mechanical complications because of underlying coagulopathy), the same strict aseptic technique, which includes full barrier precautions, must be used. However, the tip or intracutaneous segment(s) of the removed CVC should routinely be sent for culture to determine whether the insertion tract is colonized. If it is, the newly inserted CVC should be promptly removed and a new CVC placed percutaneously in a new site. If the tract is not colonized, the newly exchanged CVC can remain in the old insertion site.

Although small studies have found some utility of guidewire exchange in the management of CVCs suspected of being infected,^{352,353} we believe that, in the absence of randomized studies demonstrating its safety, guidewire exchange generally should not be performed if there is suspicion of IVD-related BSI, especially if there are signs of local infection such as purulence or erythema at the insertion site or signs of systemic sepsis without a source. In these cases the old catheter should be removed and cultured, and a new catheter should be inserted in a new site.

5. *Replacing the delivery system:* Whereas most infusion-related BSIs are caused by infection of the device used for vascular access, infusate can occasionally become contaminated and cause endemic BSIs.^{307,354} If an infusion runs continuously for an extended period, the cumulative risk of contamination increases, and there is further risk that contaminants can grow to concentrations that could produce BSI in the recipient of the fluid. For more than 25 years, most U.S. hospitals have routinely replaced the entire delivery system of patients' IV infusions at 24- or 48-hour intervals³⁵⁵ to reduce the risk of BSI from extrinsically contaminated fluid. Prospective studies indicate that IV delivery systems need not be replaced more frequently than every 72 to 96 hours, including infusions used for total parenteral nutrition or any infusions in ICU patients^{347,356}; extending the duration of use can permit cost savings to hospitals.³⁵⁶

Four clinical settings might be regarded as exceptions to using 72 hours as an interval for routine set change³⁵⁶: (1) administration of blood products, (2) administration of lipid emulsion, (3) arterial pressure monitoring, and (4) suspicion of an epidemic of infusion-related BSI. In these circumstances, it may be most prudent for administration sets to be changed routinely at 24- or 48-hour intervals.

Arterial infusions used for hemodynamic monitoring appear to be more vulnerable to becoming contaminated during use and producing endemic³⁵⁴ or epidemic septicemia,⁹⁹ caused by gram-negative bacilli. If the infusion for hemodynamic monitoring is set up so that the fluid flows continuously through the system, thus eliminating a blind stagnant column of fluid, extrinsic contamination

appears to be greatly reduced and may even eliminate the need to replace the administration set, transducer assembly, and other components of the system at frequent intervals.^{357,358} If disposable transducers are used, there appears to be no need to replace the transducer assembly and other components of the delivery system more frequently than every 4 days,³⁵⁷ and it may be safe to replace them even less frequently.³⁵⁸

6. *Anticoagulation:* Thrombus formation on an intravascular device is associated with an increased risk of infection.^{359,360} Two prospective studies have been performed to examine the efficacy of warfarin anticoagulation for reducing rates of IVD-associated thrombosis with long-term IVDs.^{361,362} Both studies found that use of warfarin in a dose of 1 mg/day was associated with significantly reduced rates of thrombosis with long-term IVDs, although no data were provided on rates of IVD-related BSI.

The use of prophylactic heparin for reducing rates of IVD-related thrombosis and infection has been evaluated in a meta-analysis.³⁶³ Examining a variety of different administration techniques in 14 randomized controlled studies, Randolph and colleagues³⁶³ concluded that systemic heparinization significantly reduced the risk of IVD-associated thrombosis (RR = 0.43, CI = 0.23 to 0.78) and device colonization (RR = 0.18, CI = 0.06 to 0.6) but failed to show a reduction in IVD-related BSIs. Heparin-bonded pulmonary artery catheters may be less prone to IVD-related BSI than nonheparinized catheters.^{307,364,365}

On the basis of these studies, low-level anticoagulation with warfarin is warranted for long-term IVDs as long as there is no contraindication (bleeding diathesis, brain tumor, or predilection to falls) and the INR (international normalized ratio) is maintained below 1.6.³⁶¹ For short-term IVDs, the use of low-dose subcutaneous heparin is more appropriate; it is commonly given to patients with CVCs or arterial lines as part of ICU thromboembolism prophylaxis.

Novel Technology

Despite compliance with recommended guidelines, many centers continue to have high rates of IVD-related BSI. Novel technology holds much promise (Box 50.3). Innovative technologies designed to reduce the risk of IVD-related BSI have proved not only to be effective but also to reduce health care costs, both with short-term and long-term IVDs.^{305,366}

1. *Novel securement devices:* In a randomized trial of a novel sutureless device for securing noncuffed vascular catheters (StatLock, Venetec International), premature loss of pediatric PICCs caused by accidental extrusion and PICC-associated thrombosis was significantly reduced,³⁶⁷ and in two additional trials the incidence of catheter-related BSI was significantly reduced with the use of the novel securement device, both in adults and children with PICCs.^{367,368}

The promise of this device for reducing infection may derive from elimination of a festering skin suture wound contiguous to the newly inserted catheter and minimizing to-and-fro movement of the catheter, which may

Anti-infective catheter hubs
 Iodinated chamber
 External povidone-iodine-saturated sponge cap

Anti-infective lock solutions for long-term IVDs
 Gentamicin
 Vancomycin
 Vancomycin-ciprofloxacin
 Trisodium citrate-gentamicin
 Minocycline-ethylenediaminetetraacetic acid (EDTA)
 Ethanol
 Taurolidine

Scheduled (prophylactic) thrombolysis with urokinase

Modified from Crnich CJ, Maki DG: The promise of novel technology for the prevention of intravascular device-related bloodstream infection. I. Pathogenesis and short-term devices. Clin Infect Dis 2002;34:1232-1242, 1362-1368.

promote invasion of the tract by cutaneous microorganisms through capillary action.³⁶⁹

2. **Novel dressings:** Studies of polyurethane dressings, which contain antiseptics such as povidone-iodine or ionized silver, have been disappointing. However, on the basis of demonstrated superiority of chlorhexidine for cutaneous disinfection of access sites, a novel chlorhexidine-impregnated sponge dressing has been developed (Biopatch, Johnson and Johnson Medical, Inc.). It maintains a high concentration of the antiseptic on the insertion site under the dressing. The largest study to date found that use of the chlorhexidine-impregnated sponge dressing was associated with a 60% reduction in catheter-related BSI (RR = 0.37, $p = 0.01$).³⁷⁰ Although

there were no adverse side effects associated with the use of this dressing in this trial in adults, a pediatric trial found that 15% of low-birth-weight neonates developed local dermatotoxicity.³⁷¹

3. **Anti-infective impregnated catheters:** Intravascular devices directly coated or impregnated with antimicrobials or antiseptics have been intensively studied over the past several decades. Eighteen randomized trials evaluating the efficacy of chlorhexidine-silver-sulfadiazine-impregnated or minocycline-rifampin-impregnated CVCs have been published in full article or abstract form since 1994.^{273,274,295,372,373}

Of the 16 published studies that examined the effect of antimicrobial-impregnated CVCs on rates of CVC-related BSI, 12 found either a statistically significant reduction or a strong trend toward a reduction in rates of CVC-related BSI.^{372,373} Aggregate analysis of the 15 studies that compared antimicrobial-impregnated CVCs with nonimpregnated CVCs,^{372,373} encompassing a total of 4250 CVCs, shows that antimicrobial-impregnated CVCs are associated with a 40% reduction in CVC-related BSI (61 BSIs/2129 devices vs. 101 BSIs/2118 devices, OR 0.60, 95% CI = 0.44 to 0.82, $p = 0.001$), a result remarkably similar to the findings of three published meta-analyses.^{305,374,375}

Finally, two rigorous and sophisticated economic analyses have found that antimicrobial-impregnated CVCs are cost effective.^{376,377} Veenstra and colleagues showed that antimicrobial-impregnated CVCs remained cost effective even if the cost of a CVC-related BSI was as low as \$687 per case; cost savings were \$196 per antimicrobial-impregnated CVC when a more realistic cost of a CVC-related BSI of \$9738 was used in the analysis.³⁷⁶ Shorr and colleagues³⁷⁷ showed that use of antimicrobial-impregnated CVCs was associated with a cost savings of \$9600 per CVC-related BSI prevented and that \$165 to \$280 would be saved for every patient who received an antimicrobial-impregnated CVC.

On the basis of this large body of data, two national advisory panels have recommended the use of antimicrobial-impregnated CVCs in clinical settings where, despite rigorous application of other preventive interventions, rates of IVD-related BSI remain unacceptably high (i.e., ≥ 3.3 BSIs per 1000 IVD-days).^{132,378}

4. **Antimicrobial lock solutions:** Given the importance of hub contamination and intraluminal colonization in the genesis of IVD-related BSI with long-term IVDs, intraluminal instillation of an antibiotic or antiseptic solution has the potential to reduce the risk of BSI associated with these devices. Six randomized, prospective trials have examined a vancomycin-containing antibiotic lock solution for the prevention of IVD-related BSI, the largest of which found that use of a vancomycin or vancomycin/ciprofloxacin lock solution reduced the risk of IVD-related BSI nearly 80% ($p = 0.005$), with no evidence that the use of the lock solution promoted colonization or infection by vancomycin-resistant bacteria or fungi.^{379,380} Yet concern about the emergence of resistance with prophylactic antibiotic-containing lock solutions has limited their wider acceptance to date. However, the use of prophylactic antibiotic lock solution is considered

acceptable in the 2011 HICPAC Guideline if a patient with an essential long-term IVD has continued to experience recurrent IVD-related BSIs despite consistent application of infection control practices.¹³²

Various other prophylactic lock solutions have been studied as a means of preventing IVD-related BSI including trisodium citrate/gentamicin,³⁸¹ minocycline/ethylenediaminetetraacetic acid (EDTA),³⁸² ethanol,³⁸³ and taurolidine-containing solutions.³⁸⁴ Concerns about increased IVD complication rates³⁸⁴ and drug-related toxicity³⁸¹ associated with the use of certain types of lock solutions, combined with the limited number of patients who have been studied while receiving these agents, precludes their routine use at this time.

5. *Catheter hubs*: A novel catheter hub that contains a chamber filled with iodinated alcohol has been shown to be effective in preventing colonization of IVDs in an animal model.³⁸⁵ Use of this same hub model in some clinical studies has demonstrated significantly lower rates of IVD colonization compared with IVDs with control hubs.^{386,387} One clinical trial has also demonstrated reduced rates of IVD-related BSIs with use of this hub (4% versus 16%, $p < 0.01$). A subsequent study also showed a reduction in hub-related IVD-related BSIs (1.7% versus 7%, $p < 0.049$), but overall rates of IVD-related BSIs in both groups were similar.³⁸⁷ Another study was unable to find any benefit with regard to IVD colonization or IVD-related BSI with use of the novel hub.³⁸⁸ This device is not yet available in the United States and until further studies more conclusively demonstrate its benefit, its use cannot be recommended at this time.

VENTILATOR-ASSOCIATED PNEUMONIA

INCIDENCE AND IMPACT

Hospital-acquired pneumonia (HAP) is defined as pneumonia that develops more than 48 hours after hospitalization.³⁸⁹ VAP is a subset of HAP and is defined as pneumonia that occurs more than 48 to 72 hours after initiating mechanical ventilation.³⁸⁹ Nearly 300,000 episodes of HAP occur in U.S. hospitals each year.³⁹⁰ More than 90% of HAPs occur in patients undergoing mechanical ventilation, and 10% to 20% of mechanically ventilated patients will develop VAP.³⁹¹ Incidence rates of VAP are highest in trauma, burn, neurosurgical, neurologic, and surgical ICUs (see Table 50.1).²⁵ VAP increases length of hospitalization by 6.1 days and health care costs by \$10,019 when compared with matched control subjects who had not developed VAP.³⁹¹ More importantly, VAP is associated with more nosocomial deaths than is infection at any other site³⁹²—at least 50,000 deaths in U.S. centers annually—and increases hospital mortality rate at least twofold in affected individuals.³⁹¹

PATHOGENESIS

In the normal nonsmoking host, multiple host defense mechanisms contribute to protection against pneumonia.³⁹³ The respiratory tract above the vocal cords is normally heavily colonized by bacteria, but unless the person has chronic bronchitis or has had respiratory tract instrumentation, the lower respiratory tract is normally sterile; although

healthy adults aspirate frequently during sleep, the lower airways and pulmonary parenchyma of healthy, nonsmoking persons without lung disease are remarkably free of microbial colonization.³⁹⁴ The major defense mechanisms include anatomic airway barriers, the cough reflex, mucus,³⁹⁵ and mucociliary clearance.³⁹⁶ Below the terminal bronchioles, the cellular and humoral immune systems are essential components of host defense.³⁹⁷ Alveolar macrophages and leukocytes remove particulate matter and potential pathogens, elaborate cytokines that activate the systemic cellular immune response, and act as antigen-presenting cells to the humoral arm of immunity.³⁹⁸ Immunoglobulins and complement opsonize bacteria and bacterial products within the respiratory tract, assisting phagocytosis.

In the mechanically ventilated patient, numerous factors conspire to compromise host defenses: Critical illness, comorbid conditions, and malnutrition impair the immune system.^{399,400} Endotracheal intubation thwarts the cough reflex; compromises mucociliary clearance; injures the tracheal epithelial surface; and provides a direct conduit for bacteria from the mouth, hypopharynx, and stomach to gain direct access to the lower respiratory tract.⁴⁰¹ Moreover, the cuff of the endotracheal tube allows pooling of oropharyngeal secretions in the subglottic region, forming an ideal medium for microbial growth, which periodically leaks around the cuff into the trachea. It would probably be more accurate pathogenically to rename VAP as “endotracheal intubation–related pneumonia.” This combination of impaired host defenses and continuous exposure of the lower respiratory tract to large numbers of potential pathogens through the endotracheal tube puts the mechanically ventilated patient at great jeopardy of developing VAP.

In order for microorganisms to cause VAP, they must first gain access to the normally sterile lower respiratory tract, where they can adhere to the mucosa and produce sustained infection. Microorganisms gain access by one of four mechanisms (Fig. 50.8): (1) aspiration of microbe-laden secretions, either from the oropharynx directly or, secondarily, by reflux from the stomach into the oropharynx, then into the lower respiratory tract⁴⁰²⁻⁴⁰⁴; (2) inhalation of contaminated air or medical aerosols⁴⁰⁵; (3) direct extension of a contiguous infection such as a pleural space infection⁴⁰⁶; or (4) hematogenous carriage of microorganisms to the lung from remote sites of local infection such as an IVD-related BSI.⁴⁰⁷

Although numerous epidemics of VAP have been caused by contaminated aerosols or medical respiratory devices,^{97,98,103} the preponderance of evidence suggests that most endemic VAPs derive from aspiration of oropharyngeal organisms^{41,408}:

- The oropharynx of critically ill patients is rapidly colonized with the pathogens that cause VAP, especially aerobic gram-negative organisms and *S. aureus*.³⁹⁹
- Studies in which multiple anatomic sites are cultured simultaneously over time have shown that the pathogenic microorganisms implicated in VAP are usually first recovered from the oropharynx and later from the tracheo-bronchial tree and stomach.^{402-404,409} Moreover, heavy oropharyngeal colonization is a powerful independent

Figure 50.8 Routes of colonization/infection in mechanically ventilated patients. Colonization of the aerodigestive tract may occur endogenously (A and B) or exogenously (C through F). Exogenous colonization may result in primary colonization of the oropharynx or may be the result of direct inoculation into the lower respiratory tract during manipulations of respiratory equipment (D), during use of respiratory devices (E), or from contaminated aerosols (F). (From Crnich CJ, Safdar NS, Maki DG: The role of the intensive care environment in the pathogenesis and prevention of ventilator-associated pneumonia. *Respir Care* 2005;50:813-836.)

predictor of subsequent tracheobronchial colonization and VAP.⁴⁰⁴

- Reducing oropharyngeal colonization with topical antimicrobials and antiseptics has been shown to significantly reduce the risk of VAP.⁴¹⁰⁻⁴¹³

By this route, aspiration of oropharyngeal contents containing a large microbial inoculum overwhelms host defenses already compromised by critical illness and the presence of an endotracheal tube, readily leading to the development of VAP.

MICROBIOLOGY

Pathogens causing VAP may be part of the host's endogenous flora at the time of hospitalization or may be acquired exogenously after admission to the health care institution from the hands, apparel, or equipment of HCWs; hospital environment; and use of invasive devices (see Fig. 50.9). The normal flora of the oropharynx in the nonintubated patient without critical illness is composed predominantly of viridans streptococci, *Haemophilus* species, and anaerobes. Salivary flow and proteins (immunoglobulin, fibronectin) are the major host factors maintaining the normal flora of the mouth (and dental plaque). Aerobic gram-negative bacilli are rarely recovered from the oral secretions of healthy patients.⁴¹⁴ During critical illness, especially in ICU patients, the oral flora shifts dramatically to a predominance of

aerobic gram-negative bacilli and *S. aureus*.³⁹⁹ Bacterial adherence to the orotracheal mucosa of the mechanically ventilated patient is assisted by reduced mucosal IgA and increased protease production, exposed and denuded mucous membranes, elevated airway pH, increased numbers of airway receptors for bacteria because of acute illness, and antimicrobial use.

Early-onset VAP, which manifests within the first 4 days of hospitalization, is most often caused by community-acquired pathogens, such as *S. pneumoniae* and *Haemophilus* species (Fig. 50.9).⁴¹⁵ However, the microbial spectrum of VAP shifts to typical nosocomial pathogens with increasing lengths of mechanical ventilation and exposure to broad-spectrum antimicrobials (see Fig. 50.10).⁴¹⁵ That the preponderance of episodes of VAP have a late onset is supported by the fact that the most common pathogens recovered from mechanically ventilated patients with pneumonia are *P. aeruginosa*, *S. aureus*, and the Enterobacteriaceae (Fig. 50.10).^{415,416} VAP is polymicrobial in up to 20% to 40% of cases. The role of anaerobic bacteria in VAP is not well defined.

DIAGNOSIS

Hospitals participating in the CDC's National Healthcare Safety Network (NHSN) use a standardized definition for clinically defined HAP^{16,17} (see Box 50.1) on the basis of clinical criteria developed empirically more than 3 decades ago⁴¹⁷: (1) systemic signs of infection—fever, tachycardia,

Figure 50.9 Microbial causes of ventilator-associated pneumonia based on increasing length of mechanical ventilation. The relative importance of each microbial category is indicated by the thickness of the bars as they progress through each stage from left to right. GNB, gram-negative bacilli; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*; VAP, ventilator-associated pneumonia. (From Park DR: The microbiology of ventilator-assisted pneumonia. *Respir Care* 2005;50:742-765.)

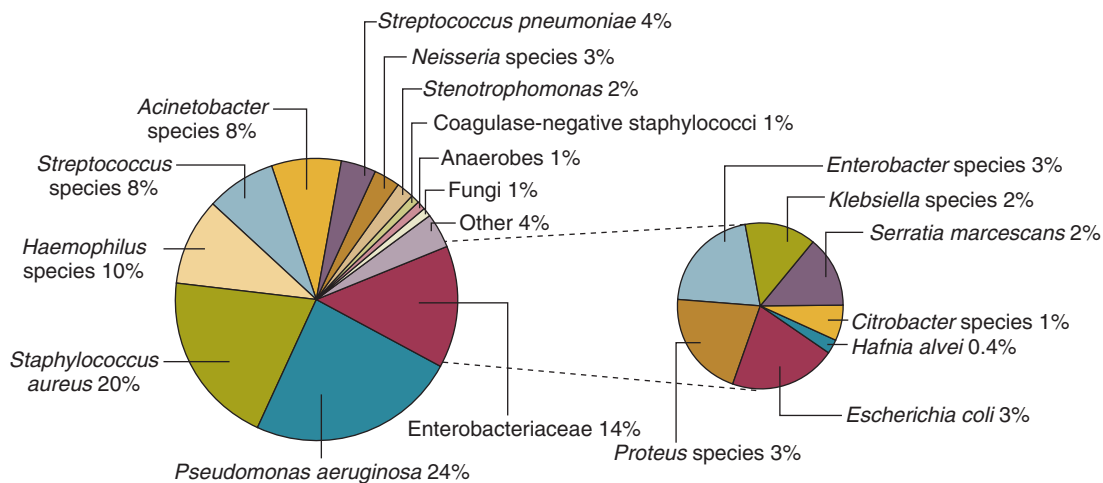

Figure 50.10 Microbial causes of ventilator-associated pneumonia. The relative proportions of microbial causes of ventilator-associated pneumonia from 1689 bronchoscopically confirmed cases involving 2490 individual isolates reported in 24 published studies. (From Park DR: The microbiology of ventilator-assisted pneumonia. *Respir Care* 2005;50:742-765.)

and leukocytosis; and (2) a new or worsening infiltrate on chest radiograph. Positive qualitative cultures of endotracheal aspirates are used to support the clinical diagnosis of HAP. Unfortunately, even when used in combination, the specificity of clinical criteria is poor, with an overall diagnostic accuracy of approximately 60% in published studies.^{418,419}

Laboratory-defined HAP (see [Box 50.1](#)) relies on more specific criteria. Most experts have advocated routine use of invasive procedures when VAP is suspected—bronchoalveolar lavage (BAL), cultures of protected specimen brush (PSB) samples obtained by bronchoscopy, or blind (mini)-BAL, on the grounds that these diagnostic techniques have comparable sensitivity, greater specificity, and superior accuracy than clinical criteria alone.^{416,420-423} Whether more rigorous clinical criteria such as the clinical

pneumonia infection score (CPIS),⁴²⁴ for example, or the use of quantitative cultures of endotracheal aspirates improve diagnostic accuracy without the need for invasive procedures is an unsettled issue.⁴²⁵

Although invasive procedures—BAL, PSB, and mini-BAL—are clearly more specific than clinical criteria, their impact on patient outcomes is much less clear.^{426,427} Fagon and colleagues⁴²⁶ found that patients with suspected VAP who were managed using an invasive diagnostic approach—bronchoscopic-guided PSB or BAL—had a significantly reduced 14-day mortality rate, reduced antibiotic-days, and reduced 28-day mortality rate on multivariate analysis, compared with patients managed using a clinical diagnostic approach (hazard ratio [HR] = 0.65, 95% CI = 0.46 to 0.91, $p = 0.01$).⁴²⁶ However, Heyland and colleagues⁴²⁷ found in a large multicenter Canadian trial that 28-day mortality

rate and targeted antimicrobial use were identical among patients randomized to an invasive versus a clinical diagnostic approach. This study has been criticized for its exclusion of subjects at high risk for infection with antimicrobial-resistant pathogens.⁴²⁸ In the absence of definitive data demonstrating the superiority of either approach, the American Thoracic Society–Society of Critical Care Medicine–Infectious Disease Society of America joint guideline acknowledges that both diagnostic approaches are useful and acceptable when evaluating patients with suspected VAP. This puts great weight on an initial Gram stain of a deep tracheal aspirate; however, if no microorganisms are seen, it can be concluded that it is unlikely the patient has bacterial VAP.³⁸⁹

RISK FACTORS

A number of independent risk factors have been shown to increase the likelihood of developing VAP (Table 50.11).^{135,416} In general, these risk factors can be categorized as (1) factors that increase the likelihood or duration of mechanical ventilation, (2) factors that increase colonization of the oropharynx and gastric mucosa, (3) factors that increase the likelihood of aspiration, and (4) host factors that increase susceptibility to infection.

Prolonged mechanical ventilation, or reintubation, or both are the most powerful predictors of developing VAP. Cunnion and colleagues⁴²⁹ found that mechanical ventilation in excess of 24 hours was associated with a 12-fold increased risk of developing VAP, and Trouillet and associates found that ventilation longer than 7 days was associated with a sixfold increased risk.⁴³⁰ Emergent reintubation also

carries a high risk of aspiration and was associated with a sixfold increased risk of VAP in a retrospective study.⁴³¹

Poor dental hygiene increases the bacterial burden in the oropharynx and is an independent risk factor for nosocomial pneumonia.⁴³² Likewise, a high gastric pH (>5) is associated with greatly increased bacterial colonization of the gastric contents,⁴³³ as well as an increased risk of VAP.⁴³⁴ A number of studies have found that exposure to antacids or H₂-blockers is associated with an increased risk of VAP,⁵⁶ although this has not been a universal finding.⁴³⁵

Depressed levels of consciousness, nasogastric tubes, and endotracheal tubes are ubiquitous in the ICU and all increase a patient's risk of aspiration. That an altered level of cognition is associated with an increased risk of aspiration is supported by surveillance data showing increased rates of VAP in trauma and neurosurgical ICUs.²⁵ Joshi and colleagues⁴³⁶ found that the use of a nasogastric tube was an independent predictor of VAP in a multivariate analysis (OR 6.5, 95% CI 2.1 to 19.8). Finally, as noted, endotracheal tubes allow pooling of hypopharyngeal secretions that can leak around the cuff directly into the trachea, and a supine position appears to increase the risk of aspiration around the cuff.⁴³⁷

Host factors also contribute to an increased risk of developing VAP (see Table 50.11). Conditions such as advanced age, increased severity of illness, and the postsurgical state are rarely modifiable. However, poor nutritional status,⁴⁰³ oversedation,⁴³⁸ transfusion therapy,⁴³⁹ and exposure to broad-spectrum antimicrobials⁴³⁰ are associated with an increased risk of VAP and are under the control of the clinician.

TREATMENT

Treatment of VAP is discussed in Chapter 42 (Pneumonia: Considerations for the Critically Ill Patient), under "Therapy."

PREVENTION

With an understanding of pathogenesis and epidemiology in hand, clinicians caring for mechanically ventilated patients can implement preventive strategies that can materially reduce the risk of VAP (Table 50.12). Both the CDC HICPAC and Canadian Critical Care Trials Group offer evidence-based guidelines for the prevention of VAP.^{135,440} Their recommendations are very similar, with minor differences. The Canadian guideline focuses exclusively on specific interventions for the prevention of VAP,⁴⁴⁰ whereas the HICPAC guideline incorporates additional guidance for the prevention of nosocomial influenza, legionellosis, and invasive filamentous fungal infections in the hospital.¹³⁵ Recommendations from both guidelines can be divided into general, nonpharmacologic, and pharmacologic preventive measures (see Table 50.12).⁴⁴¹ The general measures employed to reduce VAP including education, infection control, hand hygiene, and reliable disinfection and sterilization of respiratory care equipment are discussed elsewhere in this chapter.

Nonpharmacologic Preventive Measures

Avoiding prolonged intubation and reintubation—if avoiding intubation altogether is not feasible—offers the greatest promise for reducing an individual patient's risk of

Table 50.11 Independent Risk Factors for Ventilator-Associated Pneumonia in Multivariate Analysis of Data from Published Studies

Host Factors	Intervention Factors
Serum albumin, <2.2 g/dL	Histamine H ₂ receptor blockers ± antacids
Age, ≥60 years	Paralytic agents, continuous intravenous sedation
Acute respiratory distress syndrome (ARDS)	Receipt of >4 units of blood
Chronic obstructive pulmonary disease or other chronic pulmonary diseases	Intracranial pressure monitoring
Coma or impaired consciousness	Mechanical ventilation in excess of 48 hours
Burns, trauma	Positive end-expiratory pressure
Organ failure	Frequent ventilator circuit changes
Advanced severity of illness	Reintubation
Large-volume gastric aspiration	Nasogastric tube
Gastric colonization and high gastric pH	Supine head position
Upper respiratory tract colonization	Transport out of the intensive care unit
Sinusitis	Prior antibiotic therapy

Modified from Chastre J, Fagon JY: Ventilator-associated pneumonia. *Am J Respir Crit Care Med* 2002;165:867-903.

Table 50.12 Recommendations for the Prevention of Ventilator-Associated Pneumonia

Preventive Measure	HICPAC Grade*	CCCTG Recommendation
General Measures		
Educate all health care workers involved with the care of mechanically ventilated patients on the risks and methods of preventing ventilator-associated pneumonia.	IA	—
Perform adequate hand hygiene between patient contacts.	IA	—
Use gloves for handling respiratory secretions or objects contaminated with respiratory secretions.	IB	—
Conduct surveillance for bacterial pneumonia in ICU patients using NNIS definitions. Include data on causative organisms and their antimicrobial susceptibility patterns. Express data as rates to assist intrahospital comparisons.	IB	—
Do not routinely perform cultures of patients, equipment, or environment in the absence of an outbreak.	II	—
Thoroughly clean all devices to be sterilized and disinfected.	IA	—
Use steam sterilization or wet heat pasteurization for reprocessing of heat-stable semicritical devices and low-temperature sterilization for heat- or moisture-sensitive devices.	IA	—
Use sterile water for rinsing reusable semicritical devices.	IB	—
Change ventilator circuits only when they become soiled.	IA	Recommended
Periodically drain and discard condensate from ventilator circuits.	IB	—
Clean, disinfect, rinse with sterile water, and dry in-line nebulizers between treatments on the same patient.	IB	—
When possible, use aerosolized medications in single-use vials.	IB	—
Nonpharmacologic Measures to Reduce Pneumonia		
Oral (non-nasal) intubation	IB	Recommended
Remove nasogastric and endotracheal tubes as soon as clinically feasible.	IB	—
Avoid unnecessary reintubation.	II	—
When feasible, use noninvasive ventilation to avoid the need for intubation or reintubation.	II	—
Early tracheostomy	—	No recommendation
Semirecumbent positioning of the patient	II	Recommended
Implement a comprehensive oral hygiene program for mechanically ventilated patients.	II	—
If feasible, use an endotracheal catheter that allows for continuous or frequent subglottic suctioning.	II	Consider
Humidification with heat and moisture exchanger (HME)	NR	Recommended [†]
Closed multiuse catheters for airway secretion suctioning	NR	Recommended
Kinetic bed therapy	NR	Consider
Pharmacologic Measures to Reduce Pneumonia		
Immunize all patients at risk for pneumococcal infection.	IA	—
Immunize all patients at risk for influenza.	IA	—
Routine use of chlorhexidine oral rinse	NR	—
Targeted use of chlorhexidine oral rinse in post-cardiac surgery patients	II	—
Oral decontamination with topical antimicrobial agents	NR	—
Preferential use of sucralfate for stress bleeding prophylaxis	NR	Not recommended
Selective digestive decontamination	NR	Not recommended [‡]
Acidification of gastric feedings	NR	—
Systemic antimicrobials to prevent development of pneumonia	NR	Not recommended [‡]
Cycling of antibiotic classes to reduce resistance in the ICU	NR	—

Modified from Tablan OC, Anderson LJ, Besser R, et al: Guidelines for preventing health-care-associated pneumonia, 2003:

Recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee. *MMWR Recomm Rep* 2004;53(RR-3):1-36; and Dodek P, Keenan S, Cook D, et al: Evidence-based clinical practice guideline for the prevention of ventilator-associated pneumonia. *Ann Intern Med* 2004;141:305-313.

*Taken from CDC/HICPAC system of weighting recommendations based on scientific evidence. IA, strongly recommended for implementation and supported by well-designed experimental, clinical, or epidemiologic studies. IB, strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale. IC, required by state or federal regulations, rules, or standards. II, suggested for implementation and supported by suggestive clinical or epidemiologic trials or a theoretic rationale. Unresolved issue, an unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists. NR, no recommendation for or against at this time.

[†]Recommended in patients without hemoptysis or high minute ventilation. Exchanger should be replaced weekly.

[‡]Topical or systemic antimicrobial agents alone are not recommended. Insufficient evidence on antibiotic resistance and cost-effectiveness exists to recommend combination topical and systemic therapy.

developing VAP.⁴³¹ The use of noninvasive ventilation in order to avoid endotracheal intubation has been shown to be successful in reducing rates of nosocomial pneumonia in a number of studies^{442,443} and may abrogate the need for reintubation in selected patients who prematurely extubate themselves.¹³⁵ The implementation of weaning protocols has also been shown to significantly reduce the duration of mechanical ventilation,^{444,445} health care costs,^{444,445} and institutional rates of VAP.^{446,447} Early tracheostomy—within 1 week of intubation—has been advocated as a method for reducing the risk of VAP in patients likely to require prolonged mechanical ventilation. However, randomized trials, admittedly of limited power, have not found significant benefit with this approach⁴⁴⁸ and early tracheostomy is not currently recommended by most authorities.^{135,440}

As noted earlier, supine positioning of the mechanically ventilated patient's head has been shown to increase the risk of gastroesophageal-pharyngeal aspiration.⁴³⁷ A simple solution to this threat is to elevate the head of the patient's bed 35 to 45 degrees. Drakulovic and colleagues⁴⁴⁹ found that patients whose torso and head were kept elevated at 45 degrees had much lower rates of microbiologically confirmed pneumonia compared with patients cared for in a 0-degree supine position (5% versus 23%, $p = 0.018$).⁴⁴⁹ In reality, maintaining elevation of the head in excess of 45 degrees on a consistent basis is actually quite difficult and uncommonly achieved in practice. A recent randomized study that sought to maintain head elevation above 45 degrees for 85% of the study period found that head elevation in the intervention arm only averaged 28.1 degrees.⁴⁵⁰ Perhaps as a result of failure to successfully achieve adequate elevation, no reductions in the rate of VAP were seen.

Although data on the effect that comprehensive oral care has on risk of infection are limited,⁴⁵¹ maintaining adequate dental hygiene is considered an important component of VAP prevention.¹³⁵ Binkley and colleagues⁴⁵² found that although a majority of nurses caring for patients undergoing mechanical ventilation appreciated the importance of dental hygiene, the methods used to provide this varied considerably. Until more data are available on specific dental hygienic practices, it is recommended that mechanically ventilated patients have their teeth brushed daily, undergo oral cleansing every 2 to 4 hours, undergo routine suctioning to reduce accumulation of fluids in the oropharynx, and have a mouth moisturizer applied to their lips to prevent cracking.⁴⁵³ The periodic instillation of a topical oral antiseptic solution is an additional promising intervention⁴⁵³ and is discussed under pharmacologic preventive measures later.

The use of a modified endotracheal tube that has a separate ventral drainage tube for continuous or intermittent suctioning of subglottic secretions has been evaluated in a number of studies.^{454,455} Subglottic suctioning reduced the rate of VAP significantly in all but one of these studies.⁴⁵⁵ However, in this latter study, the time to onset of VAP was delayed significantly (5.9 days versus 2.9 days, $p = 0.006$),⁴⁵⁵ and recent evidence-based guidelines have recommended the use of endotracheal tubes that allow for suctioning of subglottic secretions.^{135,440} Nevertheless, the use of an endotracheal tube that allows for subglottic suctioning did not reduce the duration of mechanical ventilation or rate of

ICU mortality in the studies done, which, coupled with the increased cost of the tube and propensity of the suction lumen to occlude, has limited wider adoption of this technology in practice.⁴⁵⁶

The evidence that heat and moisture exchangers (HMEs) are associated with a reduced risk of VAP is mixed. Only one of six published trials found a statistically significant reduction in VAP with use of HMEs (RR 0.41, 95% CI 0.20 to 0.86, $p = 0.02$).⁴⁵⁷ However, pooling data from a recent systematic review⁴⁵⁸ and a subsequently published randomized trial⁴⁵⁹ shows that HMEs reduce the risk of VAP by 38% (RR 0.62, 95% CI 0.43 to 0.89, $p = 0.012$). The use of HMEs has been recommended by authors of a systematic review⁴⁶⁰ and is currently recommended by the Canadian Critical Care Trials Group.⁴⁴⁰ However, HICPAC made no recommendation for the use of HMEs because five of six published trials failed to demonstrate a statistically significant reduction in the rate of VAP.¹³⁵ Heat exchange moisturizers become readily occluded in patients with airway hemorrhage and can increase airway resistance. As a result, they should not be used in patients with hemoptysis or those requiring a high-minute ventilation.⁴⁴⁰ Finally, the membranes of HMEs can become colonized with bacteria and should be replaced weekly, according to current guidelines.⁴⁴⁰

The availability of in-line multiuse suction catheters abrogates the need to open and manipulate the endotracheal circuit, theoretically reducing the risk of exogenous contamination.⁴⁶¹ Despite their theoretical benefit, prospective studies have not consistently showed that in-line suction catheters are associated with a reduced risk of VAP.⁴⁶²⁻⁴⁶⁴ Although in-line suction catheters do not appear to increase the risk of VAP, they are more time efficient for nursing personnel and respiratory therapists, and are more cost effective than open suction catheters.⁴⁴⁰ Kollef and colleagues⁴⁶⁵ found that rates of VAP were identical in patients randomized to as-needed changes of their inline suction catheter versus those who had their catheter changed every 24 hours (14.7% vs. 14.8%). As a result, there is no compelling evidence that in-line suction catheters should be periodically changed, unless clinically indicated.

Pharmacologic Preventive Measures

Antacids and H₂-blockers have been used extensively in the ICU setting to prevent stress ulcer bleeding but have been associated with an increased risk of developing VAP because they lead to bacterial overgrowth of the gastric contents.⁵⁶ Sucralfate prevents stress ulcer bleeding without reducing gastric pH but is more difficult to administer and is less effective than acid-reducing agents.⁴³⁵ The results of clinical trials examining these two competing strategies for preventing gastrointestinal hemorrhage in the ICU have been mixed, with earlier trials favoring the use of sucralfate.⁵⁶ However, more recently published trials suggest only a small incremental increased risk of VAP with H₂-blockers,^{435,466,467} and most experts feel that this risk is more than offset by their superior capacity to prevent stress ulcer bleeding.^{135,440}

Selective digestive decontamination (SDD) is one of the most extensively studied preventive interventions in critical care medicine, yet the role for SDD continues to generate

vigorous debate as to its overall benefit.^{468,469} A more detailed discussion on the risks and benefits of this intervention is provided later in this chapter. Most U.S. experts believe that SDD has the potential to increase infection caused by multiresistant bacteria, particularly in settings with high rates of endemic antimicrobial resistance.^{470,471} Until well-designed multicenter trials are done, proving that SDD does not adversely effect the ICU ecology, it is likely that North American guidelines will continue to discourage its use.^{135,440}

The isolated use of parenteral antimicrobials for prevention of VAP has not met with much success,⁴⁷⁰ but selective antimicrobial decontamination of the oropharynx, without the use of enteral or systemic agents, reduced the risk of VAP nearly 70% (RR = 0.33, 95% CI 0.16 to 0.67, $p = 0.001$) in one trial.⁴¹¹ This study reemphasized the primary role of oropharyngeal colonization in the pathogenesis of VAP but engenders the same concerns as SDD over its potential for promoting antimicrobial resistance. However, it has facilitated the idea that topical decolonization of the oropharynx with *nonantimicrobial* agents might be able to materially reduce the risk of VAP without the potential for emergence of antimicrobial resistance. A meta-analysis of seven randomized trials that enrolled 914 mechanically ventilated patients found that topical chlorhexidine applied to the oropharynx reduced the risk of VAP by nearly 30% (RR = 0.74, 95% CI 0.56 to 0.96, $p = 0.02$), although there was no significant impact on mortality.⁴¹³ The beneficial effects of chlorhexidine appear to be most pronounced in post-cardiac surgery patients,^{472,473} prompting HICPAC to recommend its use in this subpopulation.¹³⁵

CATHETER-ASSOCIATED URINARY TRACT INFECTION

INCIDENCE AND IMPACT

Each year, urinary catheters are inserted in more than 5 million patients in acute-care hospitals and extended-care facilities.⁴⁷⁴ Catheter-associated urinary tract infection (CAUTI) is one of the most common infections in ICUs, and incidence rates are highest in burn, neurologic, neurosurgical, and trauma ICUs, with intermediate risk in surgical and medical ICUs, and lowest risk in coronary care units (see Table 50.1).²⁵

Nosocomial bacteriuria or candiduria develops in up to 25% of patients requiring a urinary catheter for more than 7 days, with a daily risk of 5%.⁴⁷⁴ CAUTI is the second most common cause of nosocomial bloodstream infection⁴⁷⁵; some studies have also found increased mortality rates associated with CAUTI.⁴⁷⁶ Although most CAUTIs are asymptomatic,⁴⁷⁷ rarely extend hospitalization, and add only \$500 to \$1000 to the direct costs of acute-care hospitalization,⁴⁷⁸ asymptomatic infections commonly precipitate unnecessary antimicrobial-drug therapy.⁴⁷⁹ CAUTIs comprise perhaps the largest institutional reservoir of nosocomial antibiotic-resistant pathogens, the most important of which are multidrug-resistant Enterobacteriaceae other than *Escherichia coli* such as *Klebsiella*, *Enterobacter*, *Proteus*, and *Citrobacter*; *Pseudomonas aeruginosa*; enterococci and staphylococci; and *Candida* spp.⁴⁸⁰

PATHOGENESIS

Excluding rare hematogenously derived pyelonephritis, caused almost exclusively by *S. aureus*, most microorganisms causing endemic CAUTI derive from the patient's own colonic and perineal flora or from the hands of health care personnel and gain access to the patient's urinary tract during catheter insertion or manipulation of the collection system.²⁶⁵ Organisms gain access in one of two ways. Extraluminal contamination may occur early, by direct inoculation when the catheter is inserted, or later, by organisms ascending from the perineum by capillary action in the thin mucous film between the external catheter surface and the urethral wall. Intraluminal contamination occurs by reflux of microorganisms gaining access to the catheter lumen from failure of closed drainage or contamination of urine in the collection bag. Recent studies suggest that CAUTIs most frequently stem from microorganisms gaining access to the bladder extraluminally,⁴⁸¹ but both routes are important.

Most infected urinary catheters are covered by a thick biofilm containing the infecting microorganisms embedded in a matrix of host proteins and microbial exoglycocalyx.⁴⁸² A biofilm forms on the intraluminal or extraluminal surface of the implanted catheter, or both, usually advancing in a retrograde fashion. The role of the biofilm in the pathogenesis of CAUTI has not been established. However, anti-infective-impregnated and silver-hydrogel catheters, which inhibit adherence of microorganisms to the catheter surface, significantly reduce the risk of CAUTI,⁴⁸³ particularly infections caused by gram-positive organisms or yeasts, which are most likely to be acquired extraluminally from the periurethral flora. These data suggest that microbial adherence to the catheter surface is important in the pathogenesis of many, but not all, CAUTIs. Infections in which the biofilm does not play a pathogenic role are probably caused by mass transport of intraluminal contaminants into the bladder by retrograde reflux of microbe-laden urine when a catheter or collection system is moved or manipulated.

PREVENTION

Several catheter-care practices are universally recommended to prevent or at least delay the onset of CAUTI²⁶⁵; most importantly, avoiding unnecessary catheterizations; considering using a condom catheter in a male or a suprapubic catheter; having trained professionals insert catheters aseptically; removing the catheter as soon as no longer needed; maintaining uncompromising closed drainage; ensuring dependent drainage as much as possible; minimizing manipulations of the system; and separating catheterized patients geographically on the patient care unit.

As noted earlier, technologic innovations to prevent nosocomial infection are most likely to be effective if they are based on a clear understanding of the pathogenesis and epidemiology of the infection. Novel technologies must be designed to block CAUTI by either the extraluminal or intraluminal routes, or both. Medicated catheters, which reduce adherence of microorganisms to the catheter surface, may confer the greatest benefit for preventing CAUTI. Two catheters impregnated with anti-infective solutions have been studied in randomized trials, one

impregnated with the urinary antiseptic nitrofurazone⁴⁸⁴ and the other with a new broad-spectrum antimicrobial-drug combination, minocycline and rifampin.⁴⁸⁵ Both catheters showed a modest reduction in bacterial CAUTIs; however, the studies were small, and the risk of selection of antimicrobial drug-resistant uropathogens was not satisfactorily resolved. Silver compounds have also been studied for coating urinary catheters. A meta-analysis of eight randomized trials comparing silver oxide or silver alloy catheters with standard nonimpregnated catheters found that silver alloy, but not silver oxide, catheters were associated with a reduced risk of CAUTI.⁴⁸⁶ Recommendations for the prevention of CAUTI are summarized in Table 50.13.¹³³

CONTROL OF ANTIBIOTIC RESISTANCE

During the past 55 years, more than 14 different classes of parenteral antimicrobials and several hundred antimicrobial compounds have been introduced into clinical use. In the 1960s, public health officials confidently declared that the war against infectious diseases was almost over. Unfortunately, it is not clear which side will be victorious. Although the greatest strides in our struggles with infectious diseases have resulted from improvements in hygiene and social conditions, the growing losses of our antibiotic armamentarium as a result of surging bacterial resistance could ultimately be disastrous for ICU patients if the tide is not stemmed.

EVOLUTION OF ANTIBIOTIC RESISTANCE IN INTENSIVE CARE UNITS

Antimicrobial resistance has evolved through several phases. In the 1970s and 1980s, resistance of aerobic gram-negative bacilli was the major concern, and *P. aeruginosa*, with its broad range of intrinsic and acquired resistances, was the quintessential nosocomial pathogen. By the 1990s, the availability of antibiotics from a variety of distinct classes—aminoglycosides, broad-spectrum penicillins (e.g., piperacillin), monobactams (e.g., aztreonam), carbapenems (e.g., imipenem), β -lactam- β -lactamase inhibitors (e.g., piperacillin-tazobactam), trimethoprim-sulfamethoxazole, and fluoroquinolones—promised a respite from concerns about resistance in aerobic gram-negative bacilli. During this period, however, gram-positive cocci gained prominence, and MRSA, β -lactam-resistant coagulase-negative staphylococci, and VRE became the major problem nosocomial pathogens. Antibiotic pressure, deriving first from the widespread use of third-generation cephalosporin antibiotics in hospitals, is often cited as a major factor in the emergence of MRSA. Co-emerging as nosocomial pathogens with MRSA have been methicillin-resistant coagulase-negative staphylococci, which have become the leading cause of IVD-related BSI and prosthesis-related surgical site infections.

In the early 1990s VRE burst onto the hospital and ICU scene in the United States and within a few years became entrenched in most tertiary medical centers (see Fig. 50.2). Heavy use of vancomycin, often as empiric treatment in response to concerns about MRSA, was probably the initial factor driving the emergence of VRE. In most settings, however, exposure to cephalosporins and

antimicrobials with antianaerobic activity have emerged as the greatest risk factors for nosocomial colonization or infection by VRE. The mid-1990s witnessed growing problems with resistance in fungi and shifts to non-*Candida albicans* species, representing the effects of heavy empirical use of azoles such as fluconazole in hospitals during this period.

FORCES DRIVING RESISTANCE

To a large extent, the emergence of antimicrobial resistance reflects the combined effects of genetic selection, antibiotic pressures, and the frequency of cross-infection in ICUs.⁴⁷ For some resistance mechanisms (e.g., extended-spectrum β -lactamases [ESBLs] that confer resistance to third-generation cephalosporins such as ceftazidime), a shift of a single amino acid in existing resistance genes can lead to new, inactivating enzymes. For other resistant bacteria, such as penicillin-resistant pneumococci, multiple resistance genes must be cobbled together in a specific, exacting sequence, which may take years to evolve, emerge, and spread.

Antibiotic pressures provide the necessary darwinian forces that amplify these genetic changes.⁴⁸⁷ Usually, resistance emerges to a specific agent that is used most heavily and, hence, provides the greatest pressure. In some instances, genetic linkage of resistance mechanisms to unrelated classes of antimicrobials results in the capacity of heavy use of one drug class to select for resistance to a different class. For example, use of trimethoprim-sulfamethoxazole has been associated statistically with the emergence of ceftazidime-resistant *E. coli* and *K. pneumoniae* as a result of linkage on a single plasmid of genes that encode production of ESBLs and trimethoprim-sulfamethoxazole resistance. A large proportion of extended-spectrum β -lactamase-producing gram-negative bacilli are also resistant to fluoroquinolones.^{488,489}

In epidemiologic and clinical studies of antibiotic resistance, there is always a proportion of patients in whom resistance is found without exposure to the problem antibiotic. These patients usually have other important risk factors, such as increased severity of underlying disease, extremes of age, presence of invasive devices, recent surgery, or proximity to patients who are infected or colonized with antibiotic-resistant bacteria. In these cases the presence of antibiotic-resistant strains is most often the consequence of patient-to-patient spread, usually on the contaminated hands of HCWs; occasionally, spread results from a contaminated common source, such as an inadequately cleaned piece of equipment. Studies of HCW hand hygiene show that rates of handwashing between patient contacts range from 25% to 50%, at best, and are inadequate to control resistance, especially in ICUs, where the staff are extremely busy and less likely to be attentive to hand hygiene.¹⁶⁸

CONTROLLING ANTIMICROBIAL RESISTANCE IN THE INTENSIVE CARE UNIT

Stemming the tide of antimicrobial resistance requires a multifaceted approach, especially in ICUs, where antibiotic pressures and lapses in hospital hygiene are usually greatest. First, active surveillance for resistant bacteria is essential to

provide an understanding of local problems and needs. To support surveillance and treatment, cultures must be obtained from suspected sites of infection before empiric antibiotic therapy is initiated. The benefit of routine surveillance cultures (e.g., periodic cultures of sputum specimens or rectal swabs) for assessing rates of colonization by resistant bacteria in ICUs will depend on how such cultures are used.

Second, when rates of resistance begin to increase, molecular typing, such as by pulsed-field gel electrophoresis, can differentiate spread of a single strain (clonal expansion)—which suggests person-to-person or common source transmission—from spread of multiple strains (polyclonal expansion), which suggests emergence of resistance in individual patients as a result of antibiotic pressures or exogenous introduction of multiple resistant strains. Often, these problems—clonal and polyclonal—coexist.

Third, the importance of hand hygiene must be stressed at all times. Aggressive hand hygiene campaigns, with adherence monitoring and feedback of ward and even individual results, may achieve compliance rates as high as 70%. For some situations (e.g., when there is extensive patient colonization by antibiotic-resistant bacteria), these levels of adherence may not be sufficient to control cross-infection. Response to this problem has been to encourage “universal gloving,” in addition to wider use of alcohol-based hand rubs (a “belt-and-suspender” approach) to bridge the gap left by incomplete attention to hand hygiene even in the best of circumstances. Use of universal gloving has been successful in controlling the spread of aminoglycoside-resistant gram-negative bacilli in ICUs and *C. difficile*-related diarrhea.^{228,245} Because patients’ intact skin and the environment in patient rooms may be a source of resistant bacteria, such as VRE, we recommend that disposable examination gloves be worn for all contact with ICU patients or their environment. Because gloves are not a total barrier, they must be removed and hands disinfected by an alcohol hand rub between patient contacts.

Fourth, antimicrobial stewardship is essential (Table 50.14).²⁵⁷ The primary goal of antimicrobial stewardship is to optimize clinical outcomes while minimizing unintended consequences of antimicrobial use such as toxicity, emergence of resistance, and *C. difficile*-associated diarrhea. Because antimicrobial use drives antimicrobial resistance, the frequency of inappropriate antimicrobial use can be used as a surrogate marker for antimicrobial resistance. Both antimicrobial stewardship and a comprehensive infection control program are essential to limiting the emergence and transmission of antimicrobial-resistant pathogens. Most studies assessing the utility of antimicrobial stewardship have focused on adults in ICUs, where the burden of antimicrobial resistance is greatest.

A comprehensive evidence-based stewardship program to combat antimicrobial resistance is typically a multifaceted, multidisciplinary program; the size and complexity of the management team and the specific measures applied to optimize prescribing vary on the basis of local antimicrobial use patterns, resistance trends, and available resources. The two core strategies that provide the foundation for a successful antimicrobial stewardship program are (1) prospective

audits, with intervention and feedback, and (2) formulary restriction and preauthorization.²⁵⁷

Several studies have shown that prospective audits of antimicrobial use with intervention and feedback are an effective means of reducing inappropriate antimicrobial use.^{490,491} In a randomized trial conducted at a 600-bed tertiary teaching hospital, inpatients receiving parenteral antimicrobial therapy were randomized to an intervention group that received suggestions for optimal antimicrobial use from an infectious disease physician or to no interventions. Physicians in the intervention group implemented 85% of the suggestions they received, which resulted in 1.6 fewer days of parenteral therapy and \$400 savings per patient. Similar results have been noted in trials undertaken in community hospitals.⁴⁹⁰ If daily review of antimicrobial use is not feasible, review of antimicrobial usage 3 days a week may still have a significant impact. Effective auditing with intervention and feedback can be undertaken most easily with automated computer surveillance of antimicrobial use, allowing the targeting of specific units where the problems are greatest.

Formulary restriction and preauthorization requirements for specific agents are now common in most hospitals. Antimicrobial restriction is unequivocally the most effective method of controlling antimicrobial use.^{492,493} However, it is unclear whether antimicrobial restriction achieves the more important outcome, reducing antimicrobial resistance. Several studies of outbreaks of *C. difficile*-associated diarrhea have shown abrupt cessation of the outbreak following restriction (and greatly reduced use) of one or more key antimicrobials such as clindamycin or third-generation cephalosporins.⁴⁹² However, other studies have documented inexorably rising resistance rates in nosocomial pathogens despite a rigorous program of antimicrobial restriction.⁴⁹⁴ One explanation for this increase in resistance may be the compensatory increase in usage of broad-spectrum antimicrobials other than the restricted agent, thus counteracting any benefit of restriction. Furthermore, restricting the use of a single drug to reduce antimicrobial resistance may be ineffective because cross-resistance in bacterial species to more than one class of antimicrobials is the rule in nosocomial organisms.

One or both of the core strategies should be adopted and supplemented by close collaboration among a core antimicrobial stewardship team, infection control personnel, health care providers, and hospital administration.

Beyond the two major mechanisms of antimicrobial stewardship mentioned earlier, other elements that should be incorporated into an institutional antimicrobial stewardship program include education of health care providers; however, passive educational efforts such as conference presentations, teaching sessions, and provision of guidelines are only marginally effective in the absence of other active interventions.⁴⁹⁵ Clinical practice guidelines are being introduced with increasing frequency; however, the impact of these guidelines on provider behavior and clinical outcomes has been difficult to measure. Guidelines tailored to local antimicrobial resistance patterns and antimicrobial use trends may have more impact than a generic clinical pathway.

Table 50.14 Recommendations for Developing an Institutional Program to Enhance Antimicrobial Stewardship

Recommendation	Level of Evidence*
• Create a multidisciplinary antimicrobial stewardship team, including an infectious disease physician and a clinical pharmacist with infectious disease training.	A-II
• Include, if possible, a clinical microbiologist, an information systems specialist, an infection control professional, and the hospital epidemiologist.	A-III
• Foster collaboration between the antimicrobial stewardship team and the hospital infection control committee.	A-III
• Create a climate of support and collaboration between the antimicrobial stewardship team and the hospital administration and medical staff leadership.	A-III
• Develop infrastructure to measure antimicrobial use, and track use on ongoing basis.	A-II
• Employ a system of prospective audit of antimicrobial use with direct interaction and feedback to the prescriber by an infectious disease physician or a clinical pharmacist with infectious disease training.	A-I
• Use formulary restrictions and preauthorization requirement to reduce antimicrobial use and cost.	A-II
• Provide education to health care providers regarding stewardship strategies.	A-III
• Education must be combined with active interventions to improve antimicrobial prescribing practices.	B-II
• Develop evidence-based multidisciplinary guidelines incorporating local microbiology and resistance patterns to improve antimicrobial utilization.	A-I
• No recommendation can be made regarding antimicrobial cycling as a means of preventing or reducing antimicrobial resistance.	C-II
• Use antimicrobial order forms as a component of antimicrobial stewardship.	B-II
• No recommendation can be made regarding the routine use of combination therapy to prevent emergence of resistance.	C-II
• Streamline or de-escalate antimicrobial therapy on the basis of culture results.	A-II
• Optimize antimicrobial dosing on the basis of individual patient characteristics, causative organisms, site of infection, and pharmacokinetic and pharmacodynamic characteristics of the drug.	A-II
• Use health care information technology such as electronic medical records, computerized physician order entry, and clinical decision support to improve antimicrobial prescribing.	B-II
• Use computer-based surveillance for more efficient targeting of antimicrobial interventions, tracking of resistance patterns, and identification of nosocomial infections and adverse drug reactions.	B-II
• Engage the clinical microbiology laboratory to participate in antimicrobial stewardship by providing patient-specific culture and susceptibility data and by assisting infection control efforts in the surveillance of resistant organisms and in the molecular epidemiologic investigation of outbreaks.	A-III
• Determine the impact of antimicrobial stewardship by measuring process and outcomes.	B-III

*Based on the Infectious Diseases Society of America grading system for ranking recommendations in clinical guidelines. A, good evidence to support a recommendation for use; B, moderate evidence to support a recommendation for use; C, poor evidence to support a recommendation for use; I, evidence from >1 properly randomized, controlled trial; II, evidence from >1 well-designed clinical trial, without randomization, from cohort or case-controlled analytic studies, or from multiple time-series; III, evidence from expert opinion.

Modified from Dellit TH, Owens RC, McGowan JE Jr, et al: Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America guidelines for developing an institutional program to enhance antimicrobial stewardship. *Clin Infect Dis* 2007;44:159-177.

Interest has been sparked in ICUs by the reborn concept of antibiotic cycling.^{496,497} The most recent experiences have evaluated switch therapy⁴⁹⁸ for empiric antibiotic use, rather than actual cycling, and have shown beneficial reductions in resistance among gram-negative bacilli⁴⁹⁹ and in the prevalence of VRE. Such approaches, as well as true cycling through different antimicrobial classes, may be effective over limited periods in closed environments such as ICUs, by transiently reducing selection pressure and thus resistance to the restricted agent. Yet studies have thus far not shown a consistent long-term benefit with cycling, and mathematical models do not predict that cycling will be an effective measure to reduce antimicrobial resistance.⁵⁰⁰

Antimicrobial order forms reduce antimicrobial usage with automatic stop orders and the requirement for physician justification.⁵⁰¹ Streamlining or de-escalation of

therapy based on culture data is an essential component of appropriate antimicrobial use, with studies showing substantial reductions in days of antimicrobial use and cost savings.^{502,503}

Computer order entry provides needed information at the moment in a neutral, nonjudgmental, fact-based format; this system is efficient, well accepted, and holds the promise to change prescribing behaviors materially.^{504,505}

Effective antimicrobial stewardship programs can be financially self-supporting and improve patient care. Studies have shown reductions in antimicrobial usage from 22% to 36%, with annual savings of \$200,000 to \$900,000 in larger teaching hospitals and community hospitals. A recent guideline from the Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America provides detailed recommendations for developing institutional

programs of antimicrobial stewardship, which are summarized in Table 50.14.²⁵⁷

AVANT GARDE INFECTION CONTROL MEASURES

SELECTIVE DIGESTIVE DECONTAMINATION

Intense interest has arisen in Europe and the United States⁴⁶³⁻⁴⁶⁵ over the use of “selective digestive decontamination” (SDD) for the prevention of bacterial pneumonia and other nosocomial infections in mechanically ventilated ICU patients. This novel therapy is based on the premise that the upper respiratory tract flora exists in a continuum with the gastrointestinal flora and that these mucosal microorganisms make up the major reservoir of pathogens causing pneumonia and many other nosocomial infections, especially in mechanically ventilated patients. Most ventilated ICU patients have a nasogastric tube that provides a direct conduit for reflux of microorganisms from the heavily colonized stomach to the oropharynx, from which organisms gain access to the lower respiratory tract.

SDD consists of four components: (1) a broad-spectrum parenteral antibiotic given for approximately 3 days to treat infections incubating at the time of admission to the ICU; (2) topical antimicrobials (usually polymyxin E, tobramycin, and amphotericin B) periodically applied to the oropharynx and instilled into the gut for a variable period, usually for the entire duration of ICU stay, to reduce the mucosal burden of gram-negative bacteria and yeasts while preserving the anaerobic flora; (3) a reemphasized adherence to hand hygiene to prevent nosocomial transmission of bacteria, and in some European centers, empiric barrier isolation; and (4) serial surveillance cultures of the oropharynx and rectum to monitor the efficacy of the treatment.^{506,507}

Twelve meta-analyses assessing the efficacy of SDD for reducing infection and mortality rate have been published (Table 50.15).⁵⁰⁸⁻⁵¹⁹ All have found a reduction in pneumonia. Some, but not all, have found reduced mortality rate. However, a review showed that the results of the meta-analyses were inversely related to study design,⁵²⁰ which in the case of SDD may overestimate its efficacy. Most studies and meta-analyses of SDD did not make a distinction between parenteral and topical SDD; the few meta-analyses that undertook subgroup analyses found that topical antibiotics alone reduced infection but not mortality rate.⁵¹³ A recently published large clinical trial of SDD and selective oropharyngeal decontamination in 5939 ICU patients showed a large reduction in ICU-acquired bacteremia due to gram-negative bacilli and *S. aureus*, and an estimated reduction in mortality rate of 3.5 percentage points with SDD and 2.9 percentage points with selective oropharyngeal decontamination, providing further evidence of the efficacy of SDD.⁵²¹

However, the greatest deterrent to widespread acceptance of SDD is the fear that it will promote the emergence and spread of antimicrobial-resistant microorganisms. Antibiotic pressure is without question the single most powerful force driving the selection of resistant microorganisms, and any

strategy for prevention of infection in the ICU that has the potential to increase infections caused by multiresistant organisms must be approached very cautiously. A number of studies underlie the concern of promoting antimicrobial resistance with SDD. Numerous studies have documented major shifts in the microbial ecology of the ICU with the use of SDD.⁵²²⁻⁵²⁵ In a study by Lingnau and colleagues,⁵²² 4.5 years of SDD with ciprofloxacin led to a marked increase in MRSA infection from 17% to 81% and of ciprofloxacin-resistant *S. aureus* from 33% to 80%. The number of infections caused by other multiresistant bacteria such as *Acinetobacter* was also increased by SDD.⁵²²

A distinction must also be made between the risk to an individual receiving SDD of infection caused by a resistant pathogen and the institutional risk of an increased prevalence of antimicrobial-resistant organisms related to the use of SDD. Although both consequences are undesirable, given the skyrocketing rates of endemic nosocomial MRSA and VRE infections worldwide, any—however small—potential for increased antimicrobial resistance must be taken seriously.⁵²⁶ In order to better address this issue, well-designed, cluster-randomized trials that employ multilevel modeling and specifically address the effects of SDD on antimicrobial resistance across the entire spectrum of microbial pathogens at the institutional level are necessary. Until such data are available, we believe that continued North American concerns about the effects of SDD on antimicrobial resistance are justified, particularly in institutions where MRSA and VRE are endemic, which encompasses virtually all larger hospitals. Given that other effective measures for the prevention of nosocomial infection exist, we believe that SDD should be restricted to select patients, such as certain trauma patients, or as a potential adjunctive control measure for a nosocomial outbreak caused by multiply resistant organisms.⁵²⁷

Randomized trials have identified several novel measures for prevention of VAP such as semirecumbent positioning⁴⁴⁹ and subglottic suction endotracheal tubes.⁵²⁸ We believe that these approaches are ecologically more attractive control measures for ventilated ICU patients than prophylactic topical and systemic antibiotics.

PREEMPTIVE BARRIER ISOLATION

Having fewer patients in a room, improving the facilities for handwashing, and using cohort nursing (i.e., assigning each nurse to designated patients) have reduced the incidence of endemic nosocomial infection in neonatal and pediatric ICUs.^{172,529} Complicated forms of protective isolation have reduced the high rates of nosocomial infection in patients with profound granulocytopenia⁵³⁰ or full-thickness burns.^{172,244} Moreover, the routine use of gowns and gloves on a special pediatric unit was associated with a marked decline in the incidence of nosocomial infection with RSV,⁸¹ and the routine use of gloves for all patient contacts was shown to reduce the incidence of nosocomial *C. difficile* infection nearly fivefold in a large veterans hospital.²⁴⁵

Unfortunately, the few studies that have prospectively evaluated protective isolation of ICU patients have been performed in newborns and pediatric patients and have yielded conflicting and generally disappointing results⁵³¹⁻⁵³⁴;

Studies cited in table (column 1) may be found in the complete list of references for this chapter provided online.

however, most of these studies had major weaknesses in design.²⁴⁷ More recently, several studies have shown that preemptive use of barrier precautions can effectively reduce the spread of multiresistant organisms such as MRSA or VRE in epidemic^{535,536} and endemic settings (Table 50.16).^{81,245,532,537-545} If colonization by nosocomial organisms could be prevented or at least delayed until invasive devices are removed, the incidence of infection might be significantly reduced.

One major prospective trial that assessed the efficacy of simple protective isolation—which we prefer to call *preemptive barrier precautions*—to reduce the incidence of nosocomial infection during pediatric intensive care studied 70 high-risk children over 30 months who were not immunosuppressed but who required prolonged mechanical ventilatory support and exposure to invasive devices in a pediatric ICU and were randomized to receive standard care without any special precautions or preemptive barrier isolation, with the use of disposable nonwoven polypropylene gowns and nonsterile latex gloves for all patient contacts.⁵³⁷ Risk factors predisposing patients to infection were comparable in the two groups. Nosocomial colonization occurred later among isolated patients (median 12 vs. 7 days) and was associated with subsequent infection in 2 patients, as compared with 12 patients given standard care. Among children who were isolated, the interval before the first infection was significantly longer (median, 20 vs. 8 days), the daily infection rate was twofold lower (86 vs. 44 infections per 1000 ICU days), and there were 50% fewer days with fever. The benefit of isolation was most notable after 7 days of ICU care. Isolation was well tolerated by patients and their families. Unannounced monitoring showed that children in each group were touched and handled indiscernibly by hospital personnel and families.

The study concluded that the use of disposable high-barrier gowns and gloves for the care of select high-risk children who require prolonged ICU care can substantially reduce the incidence of nosocomial infection, is well tolerated, and does not compromise the delivery of care. Simple forms of protective isolation as a general control measure would also seem preferable to attempts to suppress nosocomial colonization with SDD. Further studies are necessary to determine the cost effectiveness of prophylactic barrier precautions in the ICU and especially the efficacy of protective isolation in adult surgical ICUs, where the incidence of nosocomial infection is as high as 35%. Studies should also determine the relative importance of wearing a gown, as compared with wearing gloves alone.

Patients with prolonged severe granulocytopenia or those who are receiving high dosages of corticosteroids, usually as part of immunosuppressive regimens to prevent transplant rejection, are at risk for invasive pulmonary infection caused by *Aspergillus* species, *Zygomycetes*, and other filamentous airborne fungi, which is associated with high mortality rate.^{40-42,546} The risk of invasive infection appears to be directly related to the counts of airborne fungi, and numerous outbreaks have been linked to building construction or failure of air-control systems. Studies have shown that the isolation of vulnerable patients in positive-pressure rooms with spore-free HEPA-filtered air greatly reduces the risk of invasive infection.^{40,42} HEPA-filtered ICU rooms should be available for the care of patients who have received bone marrow or solid organ transplants and who require intensive care, especially in the early post-transplant period or during the treatment of rejection, when dosages of immunosuppressive drugs are high.

Preemptive use of barrier isolation precautions (gowns and gloves) and providing dedicated patient care items

such as stethoscopes and sphygmomanometers in all high-risk patients from the time of admission is a simple and effective strategy to prevent HCWs from acquiring hand contamination by multiresistant organisms when having contact with patients with unrecognized colonization or infection and to block transmission to other as yet uncolonized patients.

GOALS FOR THE FUTURE

Clearly, nosocomial infection is one of the most important causes of iatrogenic morbidity and death in patients who require prolonged life-support care in an ICU. Much has been learned over the past 3 decades about the relative risks and especially the pathogenesis and epidemiology of these infections, information that has provided the scientific underpinnings for preventive strategies that have proved effective. However, there is an urgent need for better research to prevent nosocomial infection in ICU patients (Box 50.4),⁶⁰⁴ particularly with respect to strategies to prevent colonization by multiresistant microorganisms, and to prevent infection even if colonization has already occurred.²⁸

Most of our understanding of the epidemiology of nosocomial infection, especially in ICUs, is based on studies of epidemics. Well-designed studies are necessary to better define the epidemiology of *endemic* nosocomial infections, especially those caused by resistant staphylococci, enterococci and gram-negative bacilli, and yeasts. The importance

of hand carriage of pathogens by hospital personnel, the role of airborne transmission in the ICU, and the relevance of contamination of the inanimate hospital environment by resistant pathogens all need to be better delineated, as well as the factors influencing nosocomial colonization and superinfection by resistant bacteria and yeasts.

In addition, larger and more sophisticated studies, using multivariate techniques of statistical analysis to define risk factors for the major forms of nosocomial infection in the ICU, are necessary to guide allocation of infection control resources and to target future research efforts.

Considering that the period of greatly increased susceptibility to infection of ICU patients is limited—until the invasive devices have been removed—a major commitment must be made to devise and evaluate strategies for blocking transmission of organisms between patients and preventing, or at least delaying, nosocomial colonization.

One of the oldest yet most important infection control measures—hand hygiene—is still done almost indifferently by HCWs in most hospitals including within ICUs. Innovative approaches are necessary to improve the frequency *and the quality* of handwashing after patient contacts likely to result in acquisition of nosocomial organisms. Exactly how should hands be washed for maximal benefit and with what agents? The question can be posed: Could very frequent handwashing, which approaches 40 times per 8-hour shift in neonatal ICUs, increase the potential for transmission of microorganisms, such as methicillin-resistant coagulase-negative staphylococci? Should the frequency of handwashing, as well as the agents used, be critically reexamined?

APPROACH TO A NOSOCOMIAL EPIDEMIC

As noted earlier, most nosocomial epidemics now occur in ICUs. If an epidemic is suspected, the epidemiologic approach must be methodical and thorough yet expeditious, directed toward establishing the bona fide nature of the putative epidemic infections (i.e., ruling out “pseudoinfections”²⁴⁶); confirming the existence of an epidemic (i.e., ruling out a “pseudoepidemic”²⁴⁶); defining the reservoirs and modes of transmission of the epidemic pathogens; and most importantly, controlling the epidemic quickly and completely. Control measures are predicated on accurate delineation of the epidemiology of the epidemic pathogen.

Each hospital, through its infection control committee, must be prepared administratively to carry out an investigation and implement needed control measures. The essential steps in dealing with a suspected outbreak of nosocomial bloodstream infection are summarized in [Box 50.E1](#).¹⁴⁶ To illustrate the approach to a nosocomial epidemic, the epidemiologic investigation of an unusual and complicated outbreak of infusion-related bacteremia³¹¹ is reviewed.

During a 2-week period in late March 1985, three patients in a university hospital developed primary nosocomial bacteremia with a similar nonfermentative gram-negative bacillus. All three patients had had open-heart surgery between March 11 and March 25 ([Fig. 50.E2](#)) and became bacteremic 48 to 148 hours after the operation.

The bloodstream pathogen in each case was shown to be *Pseudomonas pickettii* biovariant 1. The organism was also cultured from the intravenous fluid of two of the patients at the time because, serendipitously, during the outbreak most adult patients in the hospital receiving intravenous fluids were participating in a study of intravenous catheter dressings⁵⁴⁷. As part of the study protocol, specimens were routinely obtained from patients’ intravenous fluid when the catheter was removed. Review of nearly 1000 cultures of intravenous fluid from the infusions of participants in the

study since its outset 3 months earlier showed that three additional surgical patients operated on in March had had intravenous fluid cultures positive for *P. pickettii* biovariant 1 (see [Fig. 50.E2](#)), even though none had shown clinical signs of bacteremia. Molecular subtyping by restriction enzyme digestion and pulsed-field electrophoresis to delineate restriction polymorphism patterns showed all six isolates to be the clonal. Three more patients who had been operated on in January had had intravenous fluid that cultured positive for a similar nonfermentative gram-negative bacillus; although the three isolates were no longer available, the results of screening by AP-20E biochemical panel (API Analytab, Inc.) at the time were identical to those of the six patients with *P. pickettii* contamination of intravenous fluid, with or without associated bacteremia.

All three septic patients had had multiple positive blood cultures and were clinically in septic shock. *P. pickettii* had not been isolated from any local site of infection such as the urinary tract, lower respiratory tract, or surgical wound in any of the patients.

Review of nosocomial bacteremias over the past 7 years showed that *P. pickettii* had not previously been identified in any positive blood cultures from the institution, indicating that the cluster of three cases and six instances of contaminated infusate without bacteremia represented a true epidemic and, with the results of the subtyping, a common source epidemic.

The CDC and the manufacturer were contacted: None of more than 70 NNIS hospitals had reported *P. pickettii* bacteremias in the past year, and the manufacturer had never identified contamination with *P. pickettii* in quality control microbiologic sampling of its fentanyl before distribution or received any complaints from users about suspected contamination of their fentanyl. Moreover, a survey of surrounding Wisconsin hospitals that also used the manufacturer’s fentanyl revealed none experiencing nosocomial bacteremias with *P. pickettii*.

A case-control study comparing the 9 cases, all of whom had had recent surgery, with 19 operated patients who had had negative intravenous fluid cultures in the intravenous dressing study ([Table 50.E2](#)), showed that all 9 cases but

Figure 50.E2 Epidemic curve for an outbreak of *Pseudomonas pickettii* bacteremias and contaminated intravenous infusions traced to contaminated fentanyl given intravenously. Isolates from blood or intravenous fluid of six definite cases (March 1985) were available for reconfirmation and subtyping as *P. pickettii* biovariant 1; isolates from intravenous fluid of three probable cases (January 1985) were not available for retesting but were considered likely to have also been *P. pickettii* biovariant 1 on review of the results of 20 biochemical tests common to these three and the six confirmed isolates. (From Maki DG, Klein BS, McCormick RD, et al: Nosocomial *Pseudomonas pickettii* bacteremias traced to narcotic tampering. A case for selective drug screening of health care personnel. JAMA 1991;265:981-986.)

Box 50.E1 Evaluation of a Suspected Epidemic of Nosocomial Infections**Administrative Preparedness**

Immediately retrieve putative epidemic isolates for confirmation of identity through species and subtyping by one or more methods:

- Biotyping
- Antimicrobial susceptibility pattern (antibiogram)
- Serotyping
- Phage typing
- Bacteriocin typing
- SDS-PAGE protein electrophoresis
- Immunoblot pattern
- Multifocus enzyme electrophoresis
- Restriction enzyme digestion and restriction fragment polymorphism patterns
- DNA probes

Preliminary Evaluations and Control Measures

Identify and characterize individual cases in time, place, risk factors.

Strive to identify source of infections.

Ascertain whether cases represent a true infection rather than a “pseudoinfection.”

Ascertain whether cases represent a true epidemic, rather than a “pseudoepidemic.”

Develop and implement provisional control measures.

Intensify surveillance to detect each new case.

Review general infection control policies and procedures.

Determine the need for assistance, especially extramural (local, state, CDC).

Epidemiologic Investigations

- Clinicoepidemiologic studies, especially case-control studies
- Microbiologic studies

Definitive Control Measures and Follow-up

Develop and implement definitive control measures.

Confirm control of epidemic by intensified follow-up surveillance.

Reporting/Publishing Findings

Report the findings:

- Intramurally
- State health department, CDC

Publish the report.

CDC, Centers for Disease Control and Prevention; SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis.

Modified from Maki DG, Mermel LA: Infections due to infusion therapy. In Bennett JV, Brachman PS (eds): Hospital Infections, 4th ed. Boston, Lippincott-Raven, 1998.

only 9 of the 19 operated control cases had received fentanyl intravenously in the operating room ($p = 0.05$; the mean total dose given to the 9 cases was far greater than that given to control patients who received the drug, 3080 μg versus 840 μg , $p < 0.001$).

In the hospital at the time, fentanyl was used only in the operating rooms as part of balanced anesthesia. The drug was received in 20-mL ampules from the manufacturer, and each week one of three pharmacy technicians, by rotation, drew into sterile syringes all fentanyl likely to be needed the following week in the operating rooms. Each day, one of the technicians delivered enough predrawn syringes to the operating rooms to meet the needs of the cases being done that day. Cultures of predrawn fentanyl in syringes in the central pharmacy, prompted by the findings of the case-control study, showed that 20 of 50 (40%) of the 30-mL syringes sampled were contaminated by *P. pickettii*, in a concentration of greater than 10^4 CFUs/mL; none of 35 5- or 2-mL syringes showed contamination ($p = 0.001$).

Extensive culturing within the central pharmacy was negative for evidence of environmental contamination by *P. pickettii* with one exception: *P. pickettii* biovariant 1, with an identical antimicrobial susceptibility pattern and restriction enzyme fragment pattern to the epidemic strain recovered from blood cultures or patients' intravenous infusions, was cultured in a concentration of 28 to 80 CFUs/mL from five specimens of distilled water drawn from a tap in the central pharmacy. The epidemic strain was shown to multiply well in the fentanyl solution, attaining concentrations exceeding 10^4 CFUs/mL within 48 hours.

A second case-control study suggested strongly that the epidemic was caused by theft of fentanyl from 30-mL syringes by one pharmacy staff member and replacement by distilled water that the individual thought was sterile but which, unfortunately, was contaminated by *P. pickettii*. The pharmacy member resigned early in the investigation and no longer works in the hospital. On April 29, 1985, the hospital's system for providing fentanyl and other narcotics to the operating rooms was changed; narcotics are no longer pre-drawn into syringes in the central pharmacy but are delivered to the operating rooms in unopened vials or ampules, and anesthesiologists' orders for narcotics are filled by a staff pharmacist assigned to the operating room. No further bacteremias with *P. pickettii* have occurred since March 25, 1985 (see Fig. 50.E2), and cultures of more than 6000 samples of hospitalized patients' intravenous fluid in research studies since then have shown no further contamination by *P. pickettii*.

This outbreak illustrates the power of genetic subtyping¹⁵⁰ and case-control analyses to identify the cause of an epidemic. It further illustrates the potential for contamination of parenteral drugs or admixtures and the extraordinary range of epidemiologic mechanisms of nosocomial bloodstream infection deriving from such contamination.¹¹⁰

If epidemiologic or microbiologic studies suggest or indicate intrinsic contamination of a widely distributed commercial product or device, the local and state health authorities, U.S. Food and Drug Administration, CDC, and manufacturer should be informed immediately. Remaining products should be quarantined and retained for evaluation by the public health authorities.

PROTECTION OF HEALTH CARE WORKERS IN THE INTENSIVE CARE UNIT

HCWs in general, but especially those working in ICUs who are exposed daily to critically ill patients, many of whom have contagious but undiagnosed infections, are at increased risk of acquiring occupationally related infections including tuberculosis; herpes simplex virus infection; chickenpox; cytomegalovirus infection; hepatitis A, B, or C; HIV infection; influenza; measles; rubella; mumps; pertussis; and viral conjunctivitis.⁵⁴⁸⁻⁵⁵⁰

Fortunately, the risk posed by many of these infections can be eliminated by immunization of the HCW,⁵⁵¹ and recommendations from the Advisory Committee on Immunization Practices (ACIP) for the vaccination of HCWs were recently published in 2011.⁵⁵² However, a considerable number of occupational infections exist for which there are currently no vaccines.

GENERAL PRECAUTIONS AGAINST BIOHAZARDOUS EXPOSURE

All hospitals, as mandated by JCAHO,³⁰ must have an employee health service and written protocols for the

management of biohazardous exposures (Box 50.E2).^{128,553} Such protocols permit expeditious and comprehensive evaluation and timely administration of postexposure prophylaxis (PEP) with antiretrovirals after HIV exposure, immune serum globulin or hepatitis B immune globulin after exposure to hepatitis A or B, or antimicrobial prophylaxis after exposure to contagious bacterial pathogens such as *Neisseria meningitidis* or *Bordetella pertussis*.

The single greatest measure a hospital can take to reduce the risk of biohazardous exposures is to implement a comprehensive program that actively monitors occupational exposures,⁵⁵⁴ educates HCWs about the consequences and ways to prevent exposures,⁵⁵⁵ and advocates for and rigorously evaluates new safety technologies as a means of reducing exposures further.⁵⁵⁶

The importance of uncompromising compliance with universal precautions to protect HCWs from unknowing exposure to HIV and other blood-borne viruses has been discussed. Importantly, the greatest emphasis in training on universal precautions should be placed on measures to prevent needle sticks and other sharps injuries,⁵⁵³ prohibition of recapping used needles, and making impervious needle disposal containers⁵⁵⁷ available at the bedside of each ICU patient.⁵⁵⁸ The use of engineered controls such as needleless systems holds the greatest promise for effecting a material reduction in hazardous sharps injuries.⁵⁵⁶

Box 50.E2 Guidelines for Prevention and Management of Biohazardous Injuries in the Hospital*

1. Hospital personnel must be made more personally aware of the potential catastrophic sequelae of sharps injuries and other biohazardous exposures and of guidelines for prevention. This must be conveyed in initial orientation programs for all new personnel, including physicians, and by periodic updates on each patient care unit and presentations at staff conferences. The topic also can be periodically reviewed in the hospital's newsletter for personnel. Prominently placed posters warning of the hazards of sharps injuries and listing simple precautions to avert such injuries, especially in areas where sharps are heavily used, also may be of value.
 2. Sharps disposal units should be made widely and conveniently available throughout the hospital, especially in locations that facilitate their immediate use: in individual patient rooms, nursing stations, pharmacy units, and utility rooms; in all clinical laboratories; on anesthesia carts; and in each operating room. Receptacles should be made of impervious material such as plastic or metal and should be emptied according to an established routine by personnel who have been properly instructed in the correct procedure. Disposal units should consist of impervious receptacles into which a used needle and syringe or other sharps can be immediately dropped without handling it further. If it is necessary to remove a used needle from a syringe or Vacutainer, an instrument should always be used.
 3. Recapping or resheathing of used needles must be strongly discouraged except when rare circumstances do not permit immediate disposal, in which case capping must be done using a "one-handed technique" or special sheath.
 4. Medical or nursing personnel must be apprised of the importance of obtaining adequate assistance when administering injections or infusion therapy to patients who may not be able to cooperate.
 5. Personnel must be apprised of the need to use extreme care in cleaning up after procedures that involve needles or other sharps, such as lumbar punctures, thoracentesis, or central venous catheter placement.
 6. A strong institutional commitment to the continuous evaluation and selective adoption of technology-based approaches to prevention of sharps injuries will have the greatest impact.
 7. With accidental sharps injuries, unless the injury occurred with a clean sharp not used on a patient, the injury should be immediately reported to the employee health service, where work-related injuries in general can be evaluated and managed most consistently and inexpensively and surveillance of all work-related injuries can be assisted. A mechanism to ensure prompt management of biohazardous injuries 24 hours a day (including during nights and weekends by emergency department personnel who have been trained in the institutional biohazardous injury protocol) must be available.
- All hospital personnel who render care or services to patients including all staff physicians, house officers, and health care students should be covered by this institutional service to ensure consistent reporting and treatment of injuries.
- Employee health service personnel should meet with each employee who sustains a biohazardous injury, ascertain the exact reason for the accident, and review how to prevent a similar injury in the future. Particular attention should be given to those health care workers who have sustained repeated injuries, to identify accident-prone activities or individuals or high-risk work situations that should be modified.
8. Institutions should carry out continuous surveillance and reporting of all biohazardous injuries, which can form the basis for preventive programs and determine their effectiveness. Risk management personnel should include sharps injury reduction as a major institutional priority.
 9. Management of sharps injuries: A comprehensive protocol for management of sharps injuries would be beyond the scope of these guidelines; however, it is imperative that all hospitals have a protocol that provides unambiguous guidelines for management, specifically the following:
 - a. Clear definitions of biohazardous injuries
 - b. Procedures for immediate care of the injury at the time of occurrence (e.g., squeezing the puncture wound to induce bleeding, disinfection with a virucidal agent, such as an iodophor)
 - c. Procedures to determine expeditiously the magnitude of risk (i.e., screening the source patient for evidence of active infection by hepatitis B virus; hepatitis C virus; and human immunodeficiency virus [HIV]). With regard to HIV screening, the protocol must be in compliance with state statutes governing HIV testing.
 - d. The responsibilities of the injured health care worker; the worker's supervisor; the employee health service; and, after working hours, the emergency department
 - e. Guidelines for postexposure immunoprophylaxis and drug therapy, especially with exposures to the following:
 - Hepatitis A, B, and C
 - HIV infection
 - Jakob-Creutzfeldt disease
 - Syphilis
 - Malaria
 - Bacteremia
 - f. Follow-up evaluation of the exposed health care worker, especially after exposures to HIV and hepatitis B and C virus
 - g. Administrative follow-up evaluation of all injuries, to minimize recurrences, and institutional surveillance of biohazardous injuries
 - h. Periodic review of the protocol, with revision as indicated

*The Biohazardous Exposure Protocol of the University of Wisconsin Hospital and Clinics is available from the authors on request.

Modified and updated from McCormick RD, Meisch MG, Ircink FG, Maki DG: Epidemiology of hospital sharps injuries: A 14-year prospective study in the pre-AIDS and AIDS eras. *Am J Med* 1991;91:301S-307S.

VACCINE-PREVENTABLE DISEASES

HEPATITIS B

Percutaneous exposure of an unvaccinated HCW to blood from a patient who is positive for hepatitis B surface antigen (HBsAg) carries considerable risk of seroconversion (23% to 37%) and development of clinical disease (1% to 6%).¹²⁸ This risk is greatly magnified if the source patient is hepatitis B e antigen (HBeAg) positive: the risk of seroconversion is 37% to 62%, and the risk of developing clinical disease is 22% to 31%.¹²⁸ The introduction of the recombinant hepatitis B vaccine in 1986 has greatly reduced the risk of occupationally acquired disease, and it is recommended that all HCWs receive a complete three-dose hepatitis B vaccine series.^{552,559} Furthermore, ACIP recommends that all HCWs have documentation of protective serum titers (hepatitis B surface antibody [HBsAb] serum titer ≥ 10 mIU/mL) 1 to 2 months after completion of their primary series. Those HCWs who do not mount protective titers should be revaccinated with a second complete three-dose series, followed by HBsAb testing 1 to 2 months after the third dose.⁵⁵² HCWs exposed to hepatitis B who have not developed protective titers after a primary or secondary immunization series or who have not completed a primary immunization series should be given postexposure prophylaxis (PEP) as detailed by the U.S. Public Health Service,¹²⁸ or ACIP.⁵⁵²

MEASLES, MUMPS, AND RUBELLA

Reported cases of measles, mumps, and rubella have declined steadily in the United States since the introduction of mandatory childhood immunizations.⁵⁶⁰⁻⁵⁶² However, epidemics of measles and, more recently, mumps continue to be a problem in many parts of the country.⁵⁶³⁻⁵⁶⁵ Severe measles in susceptible HCWs who themselves exposed additional patients while in the incubation phase of infection have been well described in the literature.^{76,566} As a result, it is recommended that all HCWs born after 1956 have evidence of immunity to measles, mumps, and rubella by any of the following: (1) laboratory evidence of a protective titer; (2) laboratory confirmation of disease; or (3) written documentation of appropriate vaccination.⁵⁵² When nonimmune HCWs are exposed to measles, PEP with MMR vaccination has been shown to reduce the likelihood of developing fulminant disease.^{552,567} Measles immunoglobulin is another PEP option for nonimmune HCWs who have a contraindication to immunization—pregnancy—but only provides temporary protection.^{552,567} When nonimmune HCWs are exposed to mumps, PEP with MMR vaccine is not recommended for prophylactic purposes because antibody response is not believed to develop soon enough to provide effective prophylaxis; however, the first dose of MMR vaccine should be offered as soon as possible.⁵⁵² Postexposure prophylaxis for rubella with vaccine or immune globulin is not effective.⁵⁵²

VARICELLA

Occupational acquisition of varicella-zoster virus (VZV) is well described, with transmission rates among susceptible HCWs ranging from 2% to 16% in published studies.^{551,568} Infected HCWs pose a threat for transmission to other susceptible patients, and HCWs, when compared with persons who acquire varicella during adolescence, often experience

more severe disease,⁵⁶⁹ particularly if pregnant.⁵⁷⁰ All HCWs should have evidence of immunity to varicella, which includes any of the following: (1) laboratory evidence of immunity or laboratory confirmation of disease; (2) written documentation of vaccination with two doses of varicella vaccine; or (3) diagnosis or verification of a history of varicella disease or herpes zoster by a health care provider.^{552,559,571} HCWs without evidence of immunity to varicella should be given two doses of varicella vaccine administered 4 to 8 weeks apart.^{552,571}

HCWs without evidence of immunity to varicella should not care for patients with suspected or confirmed varicella or zoster infections, particularly if pregnant.⁵⁵² In the event of an accidental exposure, HCWs without evidence of immunity to varicella should be given PEP with varicella vaccine as soon as possible, and preferably within 3 to 5 days of exposure on the basis of studies demonstrating a reduced risk of developing clinical infection and attenuated clinical disease.^{552,571} For HCWs without evidence of immunity to varicella, who have been exposed to varicella or herpes zoster, and who are at high risk for severe disease and complications and for whom varicella vaccine is contraindicated (e.g., pregnant women, immunocompromised patients), varicella-zoster immune globulin is recommended as soon as possible after exposure, but can be given up to 10 days after exposure.^{552,571,572}

INFLUENZA

Influenza is responsible for 226,000 hospitalizations and 36,000 deaths in the United States each year.⁵⁷³ Nosocomial outbreaks of influenza are common and serve to put HCWs at considerable risk of acquiring and transmitting influenza to others.^{552,574,575} These outbreaks impose considerable economic burden on health care institutions and increase adverse events among HCWs and patients alike.⁵⁷⁶ Influenza immunization of HCWs has significantly reduced days of febrile illness and sick leave in randomized controlled trials,^{577,578} and surveys suggest that HCWs tend to view influenza immunization as a means of protecting themselves from illness.^{579,580} However, accumulating evidence suggests that influenza immunization of HCWs also significantly reduces rates of influenza-related morbidity and mortality among potentially exposed patients in a variety of health care settings.⁵⁸¹⁻⁵⁸³ Moreover, expanding immunization rates of HCWs has been shown to be cost saving from an institutional perspective.⁵⁸⁴ Despite this evidence, and the recommendation that all HCWs receive annual influenza vaccination,⁵⁵² voluntary immunization rates among U.S. HCWs remain disappointingly low—in the range of 40%.⁵⁸⁵ For these reasons, some experts are beginning to call for mandatory influenza immunization of HCWs (i.e., a condition of employment) in much the same way that hepatitis B and MMR vaccinations are mandatory for HCWs in most hospitals.⁵⁸⁶

PERTUSSIS

HCWs are at increased risk of developing pertussis as a result of waning immunity in adulthood,^{552,587} and numerous pertussis epidemics among HCWs have been reported in recent years.^{588,589} Pertussis outbreaks are associated with considerable economic consequences,^{589,590} and studies have shown that routinely providing a pertussis booster to HCWs

in the form of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis adsorbed vaccine (Tdap) is cost effective.⁵⁸⁹ The ACIP recommends that all HCWs receive a single dose of Tdap as soon as feasible if they have not previously received Tdap and regardless of the time since their most recent Td vaccination.⁵⁵² Despite this recommendation, Tdap vaccination coverage among HCWs in the United States remains low and was only 17% in 2009.⁵⁵²

NON-VACCINE-PREVENTABLE DISEASES OF MAJOR INTEREST

HERPETIC WHITLOW

Primary HSV paronychia has long been an occupational hazard of being an ICU nurse or physician^{591,592} and is usually associated with a great deal of pain and discomfort, fever, and lymphadenitis. Leave from work for 2 to 3 weeks is not uncommon. One of the most compelling reasons for ICU HCWs to routinely wash their hands after contact with an ICU patient and to wear gloves during any contact with a patient's airway—including gloves on *both* hands during tracheal suctioning—is to protect themselves from this miserable condition.

TUBERCULOSIS

Numerous reports of tuberculosis (TB) outbreaks in hospitals and other health care settings in the early and mid-1990s reminded the health care community of the risk associated with the care of patients with active pulmonary tuberculosis.^{73-75,238} The feature common to most of these outbreaks was failure to recognize patients with active pulmonary tuberculosis. The most important measure for preventing the transmission of tuberculosis is to (1) rapidly identify and isolate patients with suspected tuberculosis and (2) promptly initiate appropriate therapy when tuberculosis is confirmed, to reduce the duration of infectiousness.⁵⁹³ Guidelines for the prevention of nosocomial TB have been published that stress the importance of administrative, environmental, and personal respiratory protection controls.¹²⁹ Implementation of these recommendations has led to remarkable reductions in nosocomial transmission rates.²³⁹

HEPATITIS C

Nearly 4 million persons in the United States are infected with hepatitis C virus (HCV), which is responsible for 8000

to 10,000 deaths every year.⁵⁹⁴ Although the already high and rising prevalence of HCV infection in the population potentially exposes HCWs to occupationally acquired infection, most studies have failed to find a higher seroprevalence to HCV among HCWs than in the general population.⁵⁹⁵ However, at least one study found that a previous history of a needle stick injury is associated with an increased risk of HCV infection,⁵⁹⁶ and pooled analyses of published studies suggest that the seroconversion rate following a percutaneous injury involving HCV-positive persons is about 0.5%, a risk that is similar to that seen with percutaneous injuries involving needle stick exposures to HIV.⁵⁹⁵ Current guidelines for the management of HCWs exposed to HCV recommend serologic testing and measurement of serum alanine aminotransferase (ALT) levels, with or without HCV PCR testing, at baseline and again 4 to 6 months later, and do not recommend PEP with human immune globulin preparations or antiviral agents.¹²⁸ However, these recommendations may undergo modification in the near future in light of studies demonstrating sustained virological responses to interferon monotherapy in excess of 90% in patients with acute-onset HCV infection.^{597,598}

HUMAN IMMUNODEFICIENCY VIRUS

Although the risk of occupationally acquired HIV infection is low, it is not zero. As of 2002, there have been 57 probable and an additional 139 possible cases of occupationally acquired HIV in the United States.⁵⁹⁹ The vast majority involved percutaneous injuries from hollow-bore needles contaminated with blood.⁵⁹⁵ Other types of sharps injuries are less likely to transmit HIV, and only a single documented case of occupational HIV transmission caused by a body fluid exposure other than blood—bloody pleural fluid—has been reported in the literature.⁶⁰⁰ Although no randomized trials exist, there are considerable data from animal⁶⁰¹ and observational studies⁶⁰² to suggest that PEP with antiretrovirals can significantly reduce the likelihood of HIV transmission following a high-risk exposure. For this reason, the U.S. Public Health Service has issued detailed recommendations on occupational HIV PEP with the choice and number of drugs driven by characteristics of the HCW, type of exposure, and characteristics of the source patient.⁶⁰³

Box 50.4 Directions for Future Research in Nosocomial Infection Control

Studies to better define the epidemiology of endemic nosocomial infections:

- Especially those caused by resistant staphylococci, gram-negative bacilli, and *Candida*
- The relevance of hand carriage of pathogens by hospital personnel
- The role of airborne transmission
- The relative importance of contamination of the inanimate hospital environment, especially with methicillin-resistant *S. aureus*, *C. difficile*, and other resistant organisms
- The biologic factors influencing colonization by nosocomial organisms
- The factors governing superinfection by resistant bacteria and *Candida*
- Better understanding of risk factors predisposing to infection, especially in the ICU, to guide allocation of resources in infection control and focus research efforts

Innovative strategies to prevent nosocomial colonization and interrupt cross-infection, especially in ICUs:

- New approaches to improving compliance with and improving the effectiveness of handwashing between patients
- Various types of barrier precautions (forms of protective isolation)
- The true efficacy and cost-benefit ratio of selective digestive decontamination, with careful assessment of the ecologic effects of long-term use
- Dedicated device care teams
- Large, randomized clinical trials of the various cutaneous antiseptics available, with infection, rather than colonization, as the index of comparison, for handwashing by personnel, site disinfection with invasive devices, patient bathing, and decolonization

Research on devices:

- Innovative designs to implicitly reduce contamination
- Colonization-resistant polymers, possibly incorporating antimicrobials onto the surface or into the polymer itself
- Better techniques of use to enhance safety
- Cost-effective "needleless" systems to protect health care personnel
- Improved laboratory tests to identify infection more accurately and rapidly, especially tracheobronchitis and pneumonia, to reduce unnecessary antibiotic therapy yet permit early therapy to avert progression to life-threatening sepsis
- Measures to restrict and improve the use of antibiotics, especially in ICUs
- Expanded, more effective approaches to education in infection control for health care personnel, especially physicians, with respect to handwashing, use of isolation, invasive devices, and use of antibiotics

Modified from Maki DG: Risk factors for nosocomial infection in intensive care. "Devices vs. nature" and goals for the next decade. *Arch Intern Med* 1989;149:30-35.
ICU, intensive care unit.

Beyond a certain frequency, more may not necessarily be better. Should handwashing machines, which substantially augment degerming,^{605,606} be adopted widely? Could regular application of chlorhexidine-containing evaporative lotions, used without water, replace some of the conventional handwashing or at least compensate for the suboptimal handwashing currently practiced?^{225,607,608} Large clinical trials, ideally in multiple centers, are necessary to ascertain the efficacy or lack of efficacy of innovative approaches to hand degerming in reducing infections in high-risk patients, particularly in nurseries and ICUs.

Whereas SDD with topical nonabsorbable antibiotics has shown promise for the prevention of nosocomial respiratory infection in ICU patients, as noted, the potential effect on the microbial ecology of the ICU must be viewed with caution, and the cost-benefit and long-term effects of SDD need better clarification. The uses of simple barrier precautions to prevent colonization and infection have shown promise and warrant further study, especially in ICUs.

Studies have shown that the use of dedicated intravenous therapy teams, consisting of trained nurses or technicians to ensure a high level of aseptic technique during catheter insertion and in follow-up care of the catheter, has been associated with greatly reduced rates of catheter-related infection and appears to be cost effective.^{327,328,609} The use of teams of trained ICU personnel to insert all urethral catheters and provide follow-up care for these catheters, all intravascular devices, and percutaneous tubes in the ICU deserves study.

Remarkably, there have been few comparative clinical trials of the various chemical antiseptics available for disinfecting skin before inserting intravascular devices or assisting in surgery or studies of antiseptic handwashing agents. Large, randomized clinical trials, ideally in multiple centers, are necessary in which infection, rather than cutaneous colonization or positive cultures, is used as the index of comparison.

Considerable evidence indicates that the material used in construction of an implanted device plays an important role in the pathogenesis of device-related infection, namely, whether the material provides an attractive surface for adherence by pathogenic microorganisms such as coagulase-negative staphylococci. Studies are necessary to delineate fully the molecular mechanisms of microbial adherence to prosthetic surfaces to develop new materials intrinsically resistant to colonization for use with implantable devices and to design devices that intrinsically deny microbial access.

Increased use of diagnostic tests has greatly increased awareness of infectious diseases. Improved laboratory techniques to identify infection more accurately and rapidly, especially methods to reliably distinguish colonization of the lower respiratory tract from early infection that merits antimicrobial therapy, could greatly reduce unnecessary antimicrobial therapy yet detect infections earlier, before they progress to sepsis with multiple-organ failure.

Antimicrobials are not used optimally in most ICUs, and there is much overuse in hospitals, particularly of extended-spectrum penicillins and cephalosporins, carbapenems, vancomycin, and fluoroquinolones. Antibiotic pressure has had a powerful effect on the hospital

microbial ecology and, as noted previously, on the profile of nosocomial infection, especially in ICUs. We must and can do better.

Last, but certainly not least, many physicians remain remarkably oblivious to the most basic precepts of infection control, and nurses are in general far better informed and are a more effective force for ensuring compliance with infection control practices. More effective ways to communicate essential information on nosocomial infection control to hospital personnel, especially with regard to handwashing, aseptic use of devices, and antibiotic therapy, and to apply it more consistently in all hospitals, would have vast immediate benefits.

KEY POINTS

- Patients in modern-day ICUs experience rates of nosocomial infection three to five times higher than non-ICU hospitalized patients. Rates of primary bacteremia and nosocomial pneumonia are up to 10 times higher.
- Patients who are severely immunocompromised or who are critically ill and have high severity of illness scores have a substantially increased risk of nosocomial infection. However, most nosocomial infections in the ICU appear causally to be most directly related to lifesaving technology, particularly invasive devices such as endotracheal tubes and mechanical ventilatory support, urethral and intravascular catheters, and intraventricular catheters, which facilitate colonization by nosocomial organisms and greatly increase vulnerability to infection.
- The major reservoir of bacterial nosocomial pathogens, and possibly *Candida* as well, in the ICU is the colonized or infected patient. Most infections begin with nosocomial colonization by organisms acquired from the hands of noncolonized HCWs. Increasing evidence suggests that antibiotic-resistant organisms, particularly MRSA, resistant enterococci, and *C. difficile*, may also be acquired from the inanimate environment immediately surrounding the patient. *Mycobacterium tuberculosis*, *Legionella*, *Aspergillus*, influenza A virus, varicella-zoster virus, measles, mumps, and the highly virulent SARS human coronavirus are transmitted by the airborne route.
- ICUs are uniquely conducive to the epidemic spread of nosocomial organisms of all types, especially antibiotic-resistant bacteria and even *Candida*; more than half of all hospital epidemics occur in ICUs.
- An active, visible institutional infection control program can prevent up to one third of nosocomial infections. Surveillance of infection, whether total or focused, and education of all personnel are the most essential components of the program.
- Use of a chlorhexidine-containing agent for handwashing between patients will reduce endemic nosocomial infections in the ICU by at least 30%. The regular use of waterless alcohol-containing hand rubs or gels may

KEY POINTS (Continued)

- provide comparable benefit in prevention of cross-infection.
- Stringent attention to isolation precautions, especially use of disposable gloves and a gown for contacts with patients known to be infected or colonized by resistant organisms, is mandatory to minimize cross-infection and prevent outbreaks. Misuse of gloves as part of universal precautions may, paradoxically, increase the risk of nosocomial infection.
- Modern-day ICUs must have adequate numbers of special negative-pressure isolation rooms for the care of patients with suspected or proven pulmonary tuberculosis and other airborne infections, such as varicella-zoster virus.
- Patients who have undergone recent bone marrow transplants or who have received intensive chemotherapy and are experiencing prolonged severe granulocytopenia should receive ICU care in special HEPA-filtered positive-pressure isolation rooms to protect them from devastating deep *Aspergillus* and other filamentous fungal infection.
- Meticulous attention to aseptic technique and the use of *maximal* barrier precautions—long-sleeved sterile surgical gown, mask and head cover, as well as sterile gloves—during the insertion of central venous catheters; the use of 2% chlorhexidine solutions for cutaneous antisepsis; avoiding insertion into the femoral veins; and prompt removal of catheters as soon as they are no longer necessary can reduce the incidence of catheter-related bloodstream infection at least threefold.
- Studies suggest that the prophylactic use of simple barrier precautions, vis-à-vis protective isolation, may provide protection against all types of ICU-acquired infections. Protective isolation is more appealing ecologically than the use of SDD.
- Measures to avert needle sticks and other sharps injuries are the most important aspect of universal precautions; these measures are necessary to protect the HCWs from HIV and other bloodborne viruses.
- A crisis of antibiotic resistance exists in ICUs. The progressive increase in antibiotic resistance of nosocomial staphylococci (methicillin), gram-negative bacilli (aminoglycosides and expanded-spectrum β -lactams), and enterococci (vancomycin or ampicillin), and the sixfold increase in *Candida* infections during the past 2 decades indicates that it is of highest priority to reduce antimicrobial pressure within ICUs.
- Novel technology holds the greatest promise for prevention of nosocomial infection in general, particularly the development of medical devices that are intrinsically resistant to infection.
- Identifying more effective ways to communicate knowledge of infection control to hospital personnel, especially with regard to handwashing, aseptic use of devices, and antibiotic therapy, and to apply it consistently in all hospitals would have vast immediate benefits.

MINIMIZING CLINICAL RESISTANCE

CONCLUSIONS

In the critical care setting, the selection of optimal antibiotic therapy often entails a two-stage process: empiric therapy, followed by directed therapy once the pathogen and type of infection are clearly identified. [Figure 51.1](#) incorporates this progression in antibiotic therapy and summarizes some principles that contribute to the goal of preserving the antibiotic armamentarium while attempting to achieve optimal clinical efficacy—the components of antibiotic stewardship. A challenge for the critical care physician is to recognize that antibiotic therapy for critically ill patients has potential ramifications for other patients in that unit over the following weeks. If antibiotic-resistant organisms or organisms with certain virulence factors are selected by a pattern of antibiotic use, those pathogens can become part of the ecology of intensive care units (ICUs) and can then be transmitted to other patients. See [Figure 51.2](#) for clinical examples of the principles of empiric therapy. In a joint 2007 guideline paper for the development of an institutional program to enhance antimicrobial stewardship, the Infectious Diseases Society of America (IDSA) and the Society for Healthcare Epidemiology of America (SHEA) wrote on the importance of education as an essential element in any program designed to influence prescribing behavior.¹ This chapter focuses on the elements of antibiotic stewardship that play a clinically relevant role in the use of antibiotics prescribed to patients in ICUs. Knowledge of these variables is essential in clinical practice and can serve as the basis for the insights necessary for an enhanced level of antibiotic prescribing.

ADEQUACY OF INITIAL EMPIRIC ANTIBIOTIC THERAPY

For many years clinicians felt that antibiotic therapy could be adjusted on day 2 or 3 into a clinical course, once either bacterial susceptibility was known or the clinical course of the patient had been defined, with no negative aspects of such changes. Beginning in the 1990s, several reports challenging this tenet were published regarding such infectious disease processes as sepsis and ventilator-associated pneumonia (VAP).²⁻⁸ In these reports investigators used the term *inadequate* to describe situations in which the organism causing an infection was not covered with antibiotic therapy as indicated by in vitro susceptibility. The published studies exhibited variability in sample size, inconclusiveness regarding whether isolated organisms were pathogens or colonizers, and lack of consistent identification of confounders that may contribute to mortality rates. On the basis of such variables, it is not possible to definitively prove that such inadequate therapy increased mortality rates. Nevertheless, the consensus of multiple studies concerned with adequate versus inadequate initial therapy in the critically ill led to the interpretation that initial inadequate therapy contributed to mortality rates.⁹

Shortly after the reports emphasizing the importance of initial, adequate therapy, a growing awareness of other important variables that influenced clinical outcomes in ICU patients began to emerge. In a 2005 joint guideline

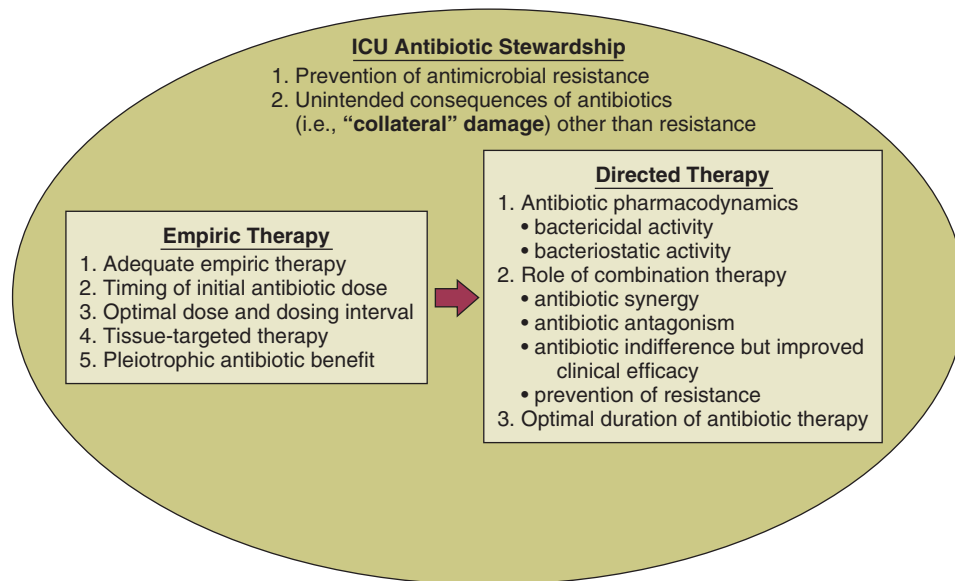

Figure 51.1 Principles governing antibiotic therapy in the intensive care unit. This concept map lists principles that influence antibiotic prescription for an individual patient, first in empiric and then in directed therapy. Antibiotic selection at all times occurs within the context of the entire intensive care unit, raising principles relevant to antibiotic stewardship that may conflict or compete with those influencing individual antibiotic prescription.

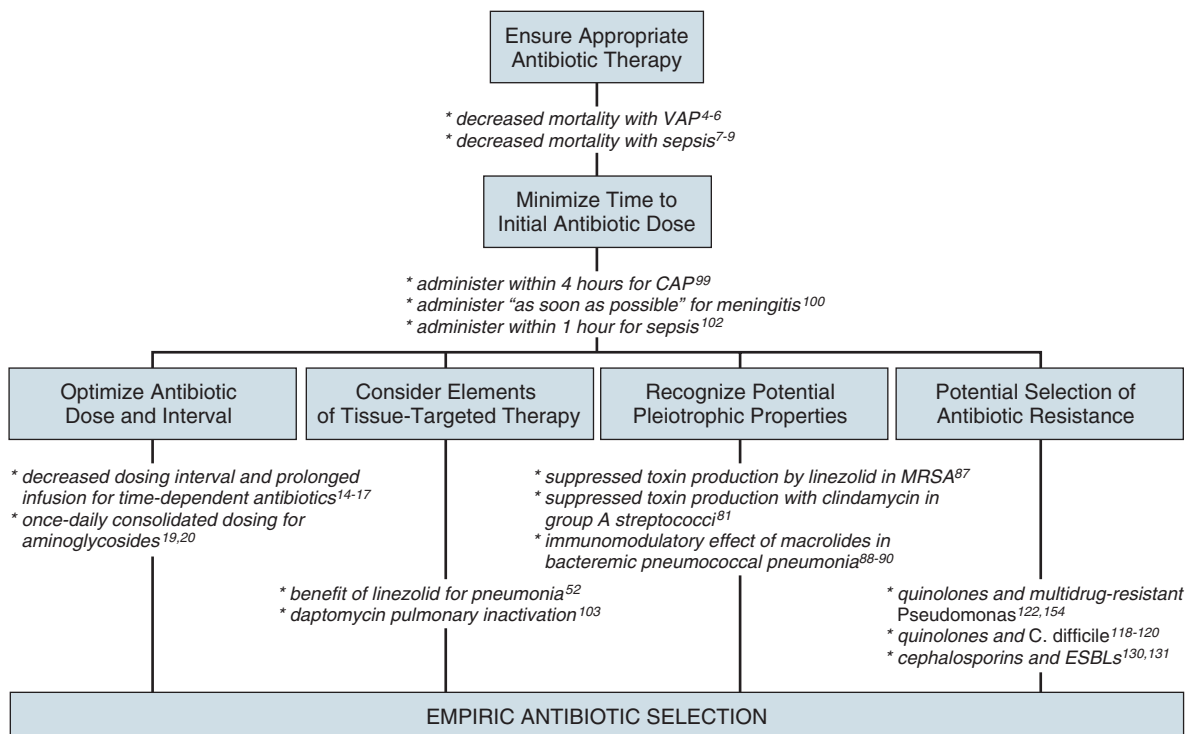

Figure 51.2 Selection of empiric antibiotic therapy in the intensive care unit. This algorithm incorporates specific examples from the text to illustrate how empiric antibiotic-prescribing principles can sequentially or concurrently influence the ultimate selection of an appropriate empiric agent.

for management of patients with hospital-acquired pneumonia (HAP), VAP, and health care–associated pneumonia (HCAP), the American Thoracic Society (ATS) and the IDSA modified definitions for the terms used in the selection of antibiotic therapy.¹⁰ *Inappropriate* replaced the term *inadequate*; furthermore, *adequate* was adopted to refer to therapy that included not only the correct antibiotic based

on the susceptibility of the organism but also optimal dose, correct route of administration, and use, if necessary, of combination therapy.¹⁰

A review of the literature suggests that other variables also play important roles in the determination of optimal clinical outcomes in patients in the ICU, including timing of antibiotic administration and certain pharmacologic properties

of the agents selected. Awareness of such factors is important in the development of the knowledge base regarding adequate antibiotic therapy and its effect on both morbidity and mortality rates. These factors are discussed next.

OPTIMAL DOSE

As the literature regarding the treatment of infections in the ICU has evolved over the years, studies have identified several elements that influence the dose of an antibiotic that is most likely to result in the best clinical efficacy. The manner in which antibiotics kill bacteria varies among different classes of drugs, but the two pharmacodynamic categories of killing that have been best categorized are *time-dependent* killing and *concentration-dependent* killing.¹¹ In time-dependent killing, also referred to as *concentration-independent* killing, maximum bacterial killing occurs when the drug concentration remains above the minimal inhibitory concentration (MIC). Examples of antibiotics that demonstrate time-dependent killing include β -lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems, and monobactams) and vancomycin. Conversely, in concentration-dependent killing, maximum bacterial killing occurs when the peak drug concentration is approximately 10 times the MIC. Examples of agents with concentration-dependent killing are fluoroquinolones and aminoglycosides. The relevance of such antibiotic properties in the management of patients with serious infections has been well demonstrated.

The pharmacologic properties of vancomycin have been nicely summarized, emphasizing the fact that vancomycin exhibits time-dependent killing.¹² Accordingly, the length of time that concentrations of vancomycin are maintained above the pathogen's MIC is critical to bacterial eradication, with a key variable in the treatment of pneumonia being the percentage of time that drug levels in the alveolar space exceed the MIC. As drug levels decline, organisms have the potential to regrow, increasing the chance of clinical failure. The clinical relevance of this pharmacologic principle may support the development of the practice habit of more frequent (every 6 hours) or continuous-infusion vancomycin dosing for infections like pneumonia in which vancomycin penetration to the target site may not be optimal.

Because a goal with time-dependent antibiotics is to maintain levels above the MIC of the organism for as long as possible during the dosing cycle, research has explored extended-infusion dosing of several time-dependent agents, including β -lactam antibiotics and vancomycin. In a study of 194 patients with infection caused by *Pseudomonas aeruginosa*, piperacillin-tazobactam was administered intravenously either every 4 to 6 hours over 30 minutes or every 8 hours over 4 hours.¹³ The 14-day mortality rate was significantly lower among patients who received extended-infusion therapy than among patients who received intermittent-infusion therapy (12.2% versus 31.6%, respectively; $P = 0.04$). In another study designed to assess blood levels of antibiotic based on both dose and pattern of administration, meropenem was administered to two study groups, each with eight healthy volunteers.¹⁴ One group received 500 mg as an intravenous infusion over 30 minutes three times a day or a 250-mg loading dose followed by a 1500-mg continuous infusion over 24 hours; the second group received 1000 mg as an intravenous infusion over 30 minutes three times a day

or a 500-mg loading dose followed by a 3000-mg continuous infusion over 24 hours. Investigators performed pharmacokinetic calculations and used Monte Carlo simulations for 10,000 simulated subjects. The results of the analyses of the probability of MIC attainment with the high dose were 4 mg/L with continuous infusion and 0.5 mg/L with intermittent infusion. With the low dose, results were 2 mg/L with continuous infusion and 0.25 mg/L with intermittent infusion. Such data emphasize that intermittent infusion of a low dose of a time-dependent drug may result in MICs adequate to treat relatively sensitive organisms such as *Klebsiella pneumoniae* but may result in less-than-optimal killing of organisms that have intrinsically higher MICs (for example, *P. aeruginosa*). Other reports have explored the efficacy of continuous-infusion vancomycin.^{15,16} A systematic review and meta-analysis suggests that extended or continuous infusion of carbapenems or piperacillin/tazobactam may be associated with lower mortality.¹⁷

The postantibiotic effect (PAE), in which microbial killing persists despite loss of detectable serum levels, complements the concentration-dependent killing of gram-negative bacilli exhibited by aminoglycosides, and these two properties may serve as the basis for once-daily aminoglycoside therapy.¹⁸ It has been suggested that giving the same total dose in larger concentration less often will result in better killing, longer PAE period, and reduced aminoglycoside toxicity that has been associated with elevated trough levels. Such pharmacologic and clinical data were the foundation for the move toward once-daily aminoglycoside dosing.

In such a dosing schedule, the single doses of gentamicin or tobramycin that have been used once daily have included 5 mg/kg and 7 mg/kg of body weight. The experience with once-daily therapy using 7 mg/kg in 2184 adult patients has been reported.¹⁹ Excluded from such therapy were patients with ascites, burns involving greater than 20% total body surface area, pregnancy, end-stage renal disease requiring dialysis, and enterococcal endocarditis. The review stated that it was unnecessary to draw standard peak and trough samples and that monitoring could be completed by obtaining a single random blood sample between 6 and 14 hours after the start of an aminoglycoside infusion. The treating clinician could subsequently adjust the dosing interval in accordance with a provided nomogram. Several important observations were made in this large group of patients: (1) Despite the prolonged drug-free period, bacterial regrowth was not clinically evident; (2) no increase in either ototoxicity or nephrotoxicity was found; and (3) efficacy was promoted in a cost-effective manner.¹⁹ A meta-analysis evaluating the safety and efficacy of once-daily aminoglycosides in 1200 patients from 16 trials found no difference concerning efficacy and safety between single-dose and multiple-dose regimens.²⁰

To achieve optimal clinical benefits while minimizing the unintended consequences of selecting resistant bacteria, clinicians must simultaneously consider multiple variables when using concentration-dependent drugs in the treatment of serious infections. In a study of lower respiratory tract infections caused by *P. aeruginosa*, ciprofloxacin was administered intravenously as a dose of 200 to 300 mg every 12 hours.²¹ Resistance emerged at a rate greater than 70% during therapy. This was similar to the 75% rate predicted by a pharmacodynamic study.²² By contrast, a randomized

comparison of imipenem and ciprofloxacin for treatment of nosocomial pneumonia used a ciprofloxacin regimen of 400 mg given intravenously every 8 hours and noted emergence of resistance during therapy in 33% of cases in which *Pseudomonas* was the causative pathogen.²³ This rate was similar to the 38% predicted by the pharmacodynamic study previously cited.²² These data emphasize the importance of considering not only the dosing interval but also the dose of antibiotic administered when using concentration-dependent antibiotics to treat infections in the critically ill.

In addition to dosing interval and initial dose, antibiotic clearance plays an integral role in adequacy of antibiotic therapy. Although it is routinely accepted that reductions in antibiotic dosing are appropriate in advancing acute kidney injury,²⁴ clinicians may fail to escalate drug administration in the increasingly reported clinical phenomenon of augmented renal clearance (ARC).²⁵ ARC is defined as the enhanced renal elimination of circulating solutes due to an increased creatinine clearance ($\text{CrCl} > 130 \text{ mL/minute/1.73 m}^2$). Prevalence of ARC is higher in burn,²⁶ major trauma,²⁷ traumatic brain injury,²⁸ and febrile neutropenic²⁹ ICU patients; however, it is difficult to traditionally recognize as derived estimates of glomerular filtration, such as the modification of diet in renal disease (MDRD) equation and Cockcroft-Gault (CG) formula are less accurate than direct measurement.³⁰ In 48 ICU patients with measured CrCl , Udy and colleagues demonstrated that CrCl values $130 \text{ mL/minute/1.73 m}^2$ or greater were associated with initial trough concentrations of β -lactams less than MIC in 82% ($P < 0.001$). Moreover, CrCl remained a significant predictor of subtherapeutic concentrations after multivariate analysis.³¹ ARC has importance in vancomycin dosing as well. Baptista and associates performed a prospective, single-center, observational cohort study of 93 consecutive septic patients in the ICU treated with vancomycin by continuous infusion after a weight-based loading dose. Investigators compared patients with and without ARC. A statistically significant correlation between subtherapeutic vancomycin serum concentration and ARC was observed in the first 3 days of treatment.³²

An interaction between renal clearance and hypoalbuminemia also plays a prominent role in pharmacokinetics. In fact, Ulldemolins and colleagues demonstrated that in critically ill patients with hypoalbuminemia, unbound flucloracillin concentrations fell below concentrations necessary for treatment of methicillin-susceptible *Staphylococcus aureus* (MSSA) 4 hours after standard bolus infusions.³³ The combination of increased volume of distribution due to hypoalbuminemia combined with ARC presents a daily situation in which lower achieved antibacterial exposures could result in subtherapeutic dosing, particularly for time-dependent antibiotics.³⁴ Because accurate and timely drug exposure is necessary for optimal clinical benefit,³ ARC and associated factors like hypoalbuminemia must be identified to prevent subtherapeutic pharmacologic treatment.

PENETRATION AT THE SITE OF INFECTION: TISSUE-TARGETED THERAPY

The importance of antibiotic pharmacokinetic properties has recently received heightened attention for the treatment

of pneumonia caused by multidrug-resistant gram-positive cocci. Indeed, pulmonary pharmacokinetics underlie the findings that the use of linezolid for pneumonia caused by methicillin-resistant *S. aureus* (MRSA), when compared with vancomycin in traditional regimens, results in improved clinical outcomes.³⁵⁻³⁸ Understanding the relevance of pharmacokinetic properties will help the critical care physician navigate through the recent published literature for these infections.

Pulmonary pharmacokinetics specifically address the tissue penetration and distribution of antibiotics within the lung.³⁹ Early studies investigating antibiotic penetration in pulmonary infections occurring in the ICU were related to aminoglycosides and fluoroquinolones. Although aminoglycoside levels in the interstitium of the lung are acceptable, levels in pulmonary secretions reach a mean of only about 20% of the concomitant serum level.⁴⁰ By contrast, the concentrations of quinolones in lung tissue significantly exceed the concomitant serum concentrations, and levels in bronchial secretions also have been reported to exceed those in serum.⁴¹ Despite the fact that quinolones have better penetration into the lung and less potential for nephrotoxicity than aminoglycosides, available data show a trend toward improved survival in patients with VAP treated with an aminoglycoside-containing, but not with a quinolone-containing, combination.⁴² A concern with fluoroquinolones in combination therapy directed against gram-negative organisms is the selection of resistance, particularly in organisms such as *P. aeruginosa*, in which the resultant resistance may be to multiple classes of antibiotics.⁴³ Because of the coexistent potential for clinical efficacy and nephrotoxicity with aminoglycosides, some investigators have suggested, on the basis of clinical trials, discontinuation of the aminoglycoside after 5 days if the patient is improving.⁴⁴

Existing pharmacokinetic evidence reveals the extremely poor lung tissue penetration of vancomycin. Cruciani and associates investigated vancomycin pharmacokinetics in 30 human lung tissue sections after administration of a 1-g dose over 1 hour.⁴⁵ A comparison of serum-to-tissue concentration over the dosing interval was used to generate a graph allowing determination of a concentration ratio. Overall, the serum-to-lung tissue concentration ratio was determined to be 21%. Not surprisingly, investigation has confirmed even poorer penetration into epithelial lining fluid.⁴⁶ These data raise concern that the traditional dosing regimens of vancomycin (1 g given intravenously every 12 hours) and low target serum trough concentrations (5 to 10 $\mu\text{g/mL}$) will generate lung tissue concentrations below the MIC for *S. aureus*. The issues surrounding suboptimal vancomycin dosing are reflected in the 2005 published ATS/IDSA guidelines for treatment for adults with HAP, VAP, and HCAP, in which it was noted that retrospective pharmacokinetic modeling suggested that the vancomycin failures may be related to inadequate dosing. Because of these concerns the authors recommend that trough levels for vancomycin should be 15 to 20 $\mu\text{g/mL}$.¹⁰ This recommendation of intensified vancomycin dosing is supported in a joint vancomycin clinical guideline for treating all complicated infectious caused by MRSA.⁴⁷

In contrast with the poor pulmonary pharmacokinetic properties of vancomycin, several studies of linezolid

confirm excellent lung penetration in healthy volunteer subjects and with in vitro modeling.⁴⁸⁻⁵⁰ Boselli and coworkers investigated the steady-state plasma pharmacokinetic variables and epithelial lining fluid concentrations of linezolid administered to critically ill patients with VAP.⁵¹ Epithelial lining fluid concentrations of linezolid approximated 100% of corresponding plasma values, with drug concentrations that exceeded the susceptibility breakpoint (4 mg/mL) for *S. aureus* throughout the greater part of the dosing interval. The principle of antibiotic pharmacokinetics has supported the conclusion that linezolid is superior to vancomycin in traditional dosing regimens for MRSA pneumonia based on retrospective analysis of the two multinational, double-blind, randomized studies published to date.³⁸ A subsequent randomized, controlled clinical trial of linezolid versus vancomycin in the treatment of nosocomial pneumonia favored linezolid; furthermore, a subgroup analysis of this investigation did not suggest a benefit in those patients with vancomycin troughs of 15 mg/L or more on day 3.⁵²

In light of the difficulty in achieving adequate drug levels in pulmonary tissue, many clinicians consider the use of topical, aerosolized antibiotics to deliver drug directly to the site of infection. The agents most commonly employed in this manner are tobramycin and colistin.⁵³ Most of our experience with, and evidence supporting, nebulized tobramycin originates from small studies and meta-analyses assessing the utility of these agents in the management of chronic respiratory disease such as cystic fibrosis, not in the treatment of acute infection.⁵⁴ Although the risk of toxicity appears lower with the administration of nebulized tobramycin, certain populations, such as those with renal insufficiency, may be at risk.⁵⁵ Because of the increasing prevalence of multidrug-resistant gram-negative organisms such as *Acinetobacter baumannii* and *P. aeruginosa*, clinicians have employed colistimethate via intravenous infusion⁵⁶ or aerosolization^{57,58} as therapy for VAP and HAP. Intravenous colistimethate appears to be safe (with a risk of nephrotoxicity similar to that for intravenous aminoglycosides) and effective, though there are few randomized, controlled trials from which to draw firm conclusions; furthermore, the optimal dosing strategy is unclear.⁵⁹ Although the aerosolized route of colistimethate administration appears to be safe,⁶⁰ its efficacy has not been established.

ROLE OF COMBINATION THERAPY

SYNERGY

One of the most frequently cited justifications for combination therapy is for the achievement of synergy, in which antimicrobial combinations are more effective than single agents. The best-recognized example of synergistic antimicrobial therapy is in treatment of enterococcal endocarditis, in which treatment with penicillin or ampicillin alone has been associated with a high rate of relapse when compared with therapy with penicillin or ampicillin in combination with streptomycin or gentamicin.^{61,62} Discussions of combination therapy have raised the question of whether the use of multiple drugs in the treatment of an infection may result in improved clinical outcomes. For example, in the treatment of bacteremia with *S. aureus*, some

investigators have used a semisynthetic penicillinase-resistant penicillin (e.g., nafcillin or oxacillin) in combination with a brief course (3 to 5 days) of an aminoglycoside, based on data showing more rapid clearing of bacteremia.⁶³ Data from this trial did not show a decrease in mortality rates in the study population of nonaddicts with primarily left-sided endocarditis caused by *S. aureus* when compared with those patients who received nafcillin alone. For *P. aeruginosa* the mechanism of synergy between antipseudomonal penicillins and aminoglycosides is similar to that of enterococci.⁶⁴ Despite this microbiologic observation, the presence or absence of synergy seemed less important in a different trial assessing outcomes in patients with *P. aeruginosa* bacteremia; rather, this investigation explored combination therapy given in an attempt to prevent the emergence of resistance.⁶⁵

In contrast with the beneficial effect of synergy, a combination regimen may result in the detrimental effect of antagonism. The classic example of such an effect was with the treatment of pneumococcal meningitis in the 1950s, in which the fatality rate among patients who received penicillin alone was 21%, in contrast with 79% among those who received both penicillin (a bactericidal agent) plus chlortetracycline (a bacteriostatic agent).⁶⁶

The clinical importance of antagonism has increased in the era of community-associated methicillin-resistant *S. aureus* (CA-MRSA). Published evidence supports the fact that MRSA is an independent predictor of mortality rate, ICU length of stay, and overall cost of care.⁶⁷⁻⁷⁰ Because a limited number of therapeutic options exist for the treatment of severe, invasive MRSA infections, effort has been made to identify the in vitro activity of antibiotic combinations that may have clinical applicability. Although the intent of using antibiotic combinations is to achieve additive or synergistic effects, the use of combinations may have the unintended effect of antagonism.

A study using 10 different strains of *S. aureus* found an overall pattern of antibiotic indifference (no combination effect) in combinations of linezolid with fusidic acid, rifampin, or gentamicin. On the other hand, the combination of linezolid with ciprofloxacin or vancomycin resulted in slight antagonism and reduced bactericidal effect when linezolid was combined with ciprofloxacin and vancomycin against the same strains of staphylococci.⁷¹ A subsequent study using the checkerboard broth microdilution method tested linezolid in combination with 28 different antimicrobial agents—including vancomycin and several fluoroquinolones—and demonstrated no antagonistic effect.⁷² Sahuquillo and colleagues reproduced the effect of antibiotic indifference with vancomycin, but they noted antagonism with levofloxacin in two of the five *S. aureus* isolates tested.⁷³

Another investigation used the rabbit model of aortic valve endocarditis to evaluate 5-day treatment regimens of linezolid alone, vancomycin alone, and linezolid in combination with vancomycin in 40 rabbits infected with an MRSA strain.⁷⁴ Those treated with vancomycin alone demonstrated greater mean reductions in valvular vegetation bacterial counts than those in the other treatment groups ($P = 0.05$). Vancomycin also sterilized aortic valve vegetations in three of eight rabbits; by contrast, none of the

rabbits treated with linezolid had sterile aortic valve vegetations. A noteworthy finding in this study was that the treatment regimen of linezolid plus vancomycin lowered the peak linezolid levels in serum to below those obtained with regimens with linezolid alone. Even though in vitro synergy testing revealed additive or indifferent activity between the two drugs, the rabbit model revealed in vivo antagonism. A potential explanation offered by the investigators for the observed antagonism between vancomycin and linezolid was the effect of combining a bacteriostatic (linezolid) with a bactericidal drug (vancomycin). The observed reduction in peak linezolid levels in serum with the combination of the two drugs suggests a role for additional mechanisms in the interaction between the two antibiotics. Unfortunately, the clinical significance of these findings is not yet known.

In the absence of definitive data on optimal management of *S. aureus* infections in seriously ill patients, a pattern has emerged in some health care systems to prescribe combination therapy for this pathogen. The overall assessment of the data is that antibiotic indifference appears to best characterize the drug interaction profile of linezolid with vancomycin. Because some data, albeit unsubstantiated in controlled clinical trials, seem to cast doubt on the advisability of the combination of linezolid with vancomycin⁷¹ and the fluoroquinolones,⁷³ it is important for the intensivist to be aware of the potential consequences of doing so. In short, the role of combination therapy in the treatment of serious MRSA infection, except in a few specific instances, is unclear.⁷⁵

ENHANCED EFFICACY AGAINST A PATHOGEN

A common question in clinical medicine is whether combination therapy will result in increased efficacy against a pathogen via a mechanism other than synergy. In an attempt to find a more definitive answer to this question, a meta-analysis of 64 trials with 7586 patients comparing β -lactam monotherapy versus β -lactam plus an aminoglycoside in immunocompetent patients with sepsis was conducted.⁷⁶ This report did not identify a statistically significant advantage of combination therapy among the 1835 patients with gram-negative infections for whom the data were analyzed. In contrast with the results in the previously cited study,⁶⁵ no improved survival was observed for the 426 patients who had infection caused by *P. aeruginosa*. An additional finding was that the rates of development of resistance did not differ in the two treatment groups. Nephrotoxicity, however, developed significantly more often in those patients who received combination therapy.

PREVENTION OF THE EMERGENCE OF RESISTANCE

Clinicians frequently use combination therapy for *P. aeruginosa* in an attempt to prevent the emergence of resistance. Despite the importance of this subject, no definitive data are available to prove that combination therapy will prevent the emergence of *Pseudomonas* resistance;⁷⁷ however, results of clinical trials²³ and concern about this possibility based on limited data have been the basis for such use of combination therapy. A meta-analysis of eight randomized controlled clinical trials compared β -lactam monotherapy and β -lactam plus aminoglycoside combination therapy to assess if

combination therapy may decrease the risk of the emergence of resistance.⁷⁸ Among initially antimicrobial-susceptible isolates in this analysis, combination therapy did not impact the development of antimicrobial resistance. Furthermore, in the meta-analysis of 64 trials comparing β -lactam monotherapy and β -lactam plus aminoglycoside combination therapy in immunocompetent patients with sepsis, there was no difference in the rate of development of resistance.⁷⁶

INCREASED OPPORTUNITY FOR ACHIEVING APPROPRIATE THERAPY

Even though issues of synergy and reduction in the emergence of resistance frequently are invoked in discussions of combination therapy, the relevant data do not prove consistent benefits. In patients in the intensive care setting, an important advantage of combination therapy is that it provides the clinician with broader antibacterial coverage for potentially multidrug-resistant microorganisms.⁷⁹ Additionally, because inappropriate initial therapy may result in increased mortality rate, a combination of antibiotics has the potential benefit of providing coverage against a pathogen that may not be the most likely on a statistical basis but is a reasonable consideration in life-threatening clinical settings confronting the critical care physician. The use of antibiotic combinations for empiric therapy increases the probability that at least one of the agents will have activity against the causative organism.

IMMUNOMODULATING EFFECT OF ANTIBIOTICS

Although most classification schemes group antibiotics according to their chemical structure and spectrum of coverage, certain antibiotics may possess additional properties that have important clinical implications. The interaction of antibiotics with host immune response, bacterial population kinetics, and bacterial gene expression for exotoxin production are examples of the pleiotropic, or “off target,” properties of antibiotics. For the critical care physician, this is especially relevant in the treatment of life-threatening infection caused by gram-positive cocci and may be the basis for combination therapy in the treatment of infections caused by such pathogens.

Streptococcal toxic shock syndrome is a clinical infection in which bacteria produce exotoxins that act as host superantigens, precipitating shock, multiple organ failure, and death. Although *Streptococcus pyogenes* demonstrates exquisite in vitro sensitivity to penicillin, experimental studies of infection by this pathogen have demonstrated reduced efficacy against organisms in the stationary phase of bacterial growth. This phenomenon has been termed the Eagle effect, whereby high organism population density and slow organism division make treatment with an antibiotic dependent on cell wall synthesis ineffective.⁸⁰ Some cite the Eagle effect as a justification for use of the bacteriostatic antibiotic clindamycin in the treatment of toxic shock syndrome. In addition, clindamycin is an antibiotic that inhibits bacterial protein synthesis, and this pharmacodynamic property is independent of the stage of bacterial growth.⁸¹ Clindamycin inhibits bacterial exotoxin production, facilitates phagocytosis of *S. pyogenes* by inhibiting M protein synthesis, and

suppresses the production of penicillin-binding proteins (PBPs). Furthermore, evidence exists that demonstrates clindamycin has immunomodulatory effects, suppressing monocyte synthesis of tumor necrosis factor- α (TNF- α).^{82,83} All of these pleiotropic qualities have resulted in the recommendation for clindamycin use in necrotizing skin or soft tissue infections and toxic shock syndrome caused by *S. pyogenes*.⁸¹

The dramatic increase in the worldwide incidence of highly virulent, community-acquired infection with CA-MRSA has resulted in increasing reports of necrotizing skin and soft tissue infections as well as necrotizing pneumonia confronting the critical care physician.⁸⁴⁻⁸⁶ CA-MRSA virulence has been attributed to expression of several virulence factors: α -hemolysins (AH), toxic shock syndrome toxin-1 (TSST-1), staphylococcal enterotoxin B, and Panton-Valentine leukocidin (PVL). The association of staphylococcal virulence with the current CA-MRSA epidemic prompted Stevens and colleagues to investigate the impact of antibiotics on the expression of virulence-associated exotoxin genes.⁸⁷ These investigators were able to demonstrate markedly suppressed in vitro production of staphylococcal toxin genes by clindamycin and linezolid such that no PVL production was noted up to 12 hours after antibiotic administration. Of interest, subinhibitory concentrations of the cell wall-active agent nafcillin were found to increase toxin production. These findings led the investigators to conclude that the inhibition of protein synthesis is an important consideration in the selection of antimicrobial agents for treatment of serious infections caused by toxin-producing gram-positive cocci.⁸⁷

A growing body of evidence exists to support the benefit of macrolide therapy for bacteremic pneumonia caused by *Streptococcus pneumoniae*.⁸⁸⁻⁹⁶ Although multiple explanations have been proposed, efficacy appears to extend beyond the drug's spectrum of antimicrobial activity. The macrolide class of antibiotics exerts a broad range of immunomodulatory effects, including suppression of harmful interleukin host responses and inhibition of neutrophil oxidant burst and degranulation.⁸⁸⁻⁹⁰ These pleiotropic effects have received an increasing focus of attention and further illustrate how immune modulation influences recommendations for therapy in the intensive care setting.

TIMING

The impact of the timing of antibiotic therapy has been addressed in several ways with regard to patients in the ICU. In an analysis based on 107 consecutive patients receiving mechanical ventilation and antibiotic treatment for VAP, Iregui and colleagues noted that 30.8% (33 of 107) received antibiotic treatment that was delayed for 24 hours or more after initially meeting diagnostic criteria for VAP; these patients were classified as having initially delayed appropriate antibiotic therapy (IDAAT).⁹⁷ Two major variables were identified in these patients with IDAAT: (1) a delay in writing an antibiotic order (in 75.8% of the cases); and (2) the presence of a bacterial species resistant to the initially prescribed antibiotic regimen (in 18.2%). The investigators found that hospital mortality rate was 69.7% for the patients with IDAAT, in contrast with only 28.4% for the patients without IDAAT ($P < 0.01$). An earlier study noted that, in

patients with VAP, modification of the antibiotic regimen to cover pathogens based on the susceptibility report did not eliminate the increased mortality rate associated with inadequate empiric therapy.⁵ Acknowledgment of this finding was the basis for the statement that secondary modifications of an initially failing antibiotic regimen do not substantially improve the outcome for critically ill patients.⁹⁸ These results challenge the clinician to promptly order antibiotics that cover the involved pathogens even before culture results are available.

The importance of antibiotic timing in patients with community-acquired pneumonia was assessed in a retrospective cohort study of pneumonia in 18,209 Medicare patients.⁹⁹ In this trial, conducted in a random sample of inpatients 65 years of age or older with community-acquired pneumonia who had not received antibiotics as outpatients, the influence on clinical outcome was assessed for use of antibiotics prescribed according to standard guidelines published at the time of the analysis and not identification of pathogens isolated from the patients. Of the patients who received antibiotics within 4 hours of hospital arrival, 83.2% were prescribed a guideline-recommended regimen, in contrast with 71.8% of the patients who received antibiotics after 4 hours of arrival. The results of this analysis found an association between the administration of antibiotics within 4 hours of hospital arrival and a decrease in mortality rate and length of stay. The investigators postulated that antibiotics may interrupt or minimize the effects of the acute lung injury process that occurs as part of the systemic inflammatory response in patients with bacterial pneumonia.

The IDSA practice guidelines for management of adult patients with meningitis note the lack of prospective clinical data on the relationship of the timing of antimicrobial administration of antimicrobial agents to clinical outcome in patients with bacterial meningitis.¹⁰⁰ Data from a retrospective cohort study of 269 adult patients with community-acquired bacterial meningitis provide some insights into the timing of antibiotic therapy in the absence of definitive recommendations.¹⁰¹ Using these and other data, the IDSA acknowledged that evidence for definitive recommendations is inadequate and concluded that a reasonable assumption is to administer treatment for bacterial meningitis before the infection advances to a high level of clinical severity.¹⁰⁰ Referring to meningitis as a “neurologic emergency,” the guideline recommended that appropriate therapy for meningitis be initiated as soon as possible after the diagnosis is considered to be likely.¹⁰⁰ In support of the importance of prompt timing, this document also noted the potential in certain patients for administration of antibiotics before hospital admission if the patient initially presents outside the hospital.

For the critical care clinician, sepsis is a clinical entity in which adequate antibiotic therapy has been associated with improved clinical outcomes.^{2,3,7,8,79} In recognition of the importance of prompt therapy in influencing clinical outcomes in patients with sepsis, the 2008 Surviving Sepsis Campaign guidelines offered a specific recommendation regarding the timing of antimicrobial therapy for the septic patient: “Intravenous antibiotic therapy should be started as early as possible and within the first hour of recognition of septic shock and severe sepsis without septic shock.

Appropriate cultures should be obtained before initiating antibiotic therapy but should not prevent prompt administration of antimicrobial therapy.”¹⁰²

SPECIAL PHARMACOLOGIC PROPERTIES

As the focus of antibiotic research has expanded beyond the characterization of in vitro properties for a particular agent, the importance of antibiotic performance at the in vivo target tissue level is becoming increasingly recognized. It was with the 2003 introduction of a novel antibiotic, daptomycin, for treatment of infections caused by resistant gram-positive cocci that the relevance of “organ-specific deactivation” initially was described.¹⁰³ Daptomycin is an intravenous cyclic lipopeptide with rapid, concentration-dependent killing and bactericidal activity against a broad spectrum of gram-positive cocci.¹⁰⁴⁻¹⁰⁶ It demonstrates a unique mechanism of action, with calcium-dependent insertion into the phospholipid bacterial cell membrane. This results in cell depolarization via potassium efflux, causing disruption of DNA, RNA, and protein synthesis.¹⁰⁷

As a result of two multicenter, randomized controlled trials comparing it with penicillinase-resistant penicillin or vancomycin,¹⁰⁸ daptomycin, at a daily dose of 4 mg/kg (for patients with CrCl greater than 30 mL/minute), received U.S. Food and Drug Administration (FDA) approval for the treatment of complicated skin and soft tissue infections. A subsequent randomized, open-label trial investigated use of daptomycin in *S. aureus* bacteremia and endocarditis.¹⁰⁹ This trial prompted FDA approval of daptomycin for treatment of *S. aureus* bacteremia, including right-sided endocarditis, at a daily intravenous dose of 6 mg/kg.

Phase 3 clinical trials also were conducted for the treatment of community-acquired pneumonia in hospitalized patients. Despite daptomycin’s potent in vitro bactericidal activity against *S. pneumoniae*, clinical outcomes were disappointing and inferior to those with the comparator, ceftriaxone. Although daptomycin is known to exhibit poor penetration into epithelial lining fluid, the reason for treatment failure was not fully elucidated until Silverman and colleagues described a unique organ-specific inactivation process.¹⁰³ Daptomycin’s inactivation was linked to its mechanism of bactericidal action: calcium-dependent membrane lipid binding.^{103,107,110,111} Using a mouse model, investigators demonstrated drug sequestration and inactivation by binding to phospholipid vesicles that are found in pulmonary surfactant.¹⁰³ For this reason daptomycin is not considered an appropriate therapeutic agent for treatment of pneumonia, largely because of the presence of surfactant at the target tissue. This phenomenon appears to be unique to daptomycin¹⁰³ but raises the question of unrecognized organ-specific inactivation for other classes of antibiotics and other target organs.

Recent antibiotic developments have introduced the possibility of managing life-threatening infections with antimicrobial agents administered at a prolonged dosing interval. A long drug half-life ($T_{1/2}$) is conducive to completion of treatment courses in the outpatient setting and maximizes patient compliance. In the context of critical care, exploiting an antibiotic’s $T_{1/2}$ historically has been used in settings such as hemodialysis with end-stage renal disease. Less frequent antibiotic dosing diminishes the burden of

intravenous access and increases the possibility of treatment outside an intensive care environment.

UNINTENDED CONSEQUENCES OF ANTIBIOTIC THERAPY

Traditional teaching about antibiotics focused on three classic parameters: efficacy, safety, and cost-effectiveness. With respect to safety, the major considerations were allergic reactions and adverse effects. Within the pandemic of antibiotic resistance, an important new safety issue should be added: unintended consequences of antibiotic therapy. An insightful report termed such unintended consequences the “collateral damage” of antibiotics.¹¹² In this report, *collateral damage* referred to the ecologic adverse effect of selecting drug-resistant organisms and the unwanted development of colonization or infection with multidrug-resistant organisms. Some important new considerations recently described in the literature, however, may influence initial antibiotic selection for serious infections in the ICU.

The increasing prevalence of MRSA infections in patients in the critical care setting has required an ongoing evaluation of factors that propagate and sustain such a pattern of resistance. The role of inadequate handwashing in the spread of nosocomial MRSA in hospitals has been well known for many years.¹¹³ As rates of MRSA have increased in infections such as HAP,¹¹⁴ increased emphasis has been placed on other variables that contribute to the role that MRSA now plays as the etiologic agent of HAP and VAP. In recognition of the infectious disease concept that colonization is an antecedent event to infection, attention has been directed to factors that may increase colonization by MRSA. Bisognano and colleagues provided preliminary evidence by evaluating the occurrence and frequency of increased adhesion in clinical isolates of fluoroquinolone-resistant MRSA and MSSA. This increased adhesion was mediated by fluoroquinolone-induced increases in fibronectin-binding proteins (FnBPs).¹¹⁵ Although this report does not prove that suboptimal levels of fluoroquinolones contribute in a clinically significant way to increased production of FnBPs and higher levels of bacterial attachment, the data do challenge the clinician to consider unintended antibiotic consequences as an explanation for increasing rates of infection with MRSA.

In addition to infection with MRSA, a problem that has gained increasing attention in recent years has been infection by strains of *Clostridium difficile* with markedly increased levels of toxin production.¹¹⁶ A postulated cause for this increase in toxin production is the phenomenon of hypermutation. Spontaneous mutations that lead to bacterial resistance occur with a frequency that generally is in the range from 10^{-6} to 10^{-8} . Hypermutation has been used to refer to a situation in which the mutation rate exceeds that recognized for spontaneous mutations.¹¹⁷ Certain factors may lead to genetic damage in bacteria with a resultant increase in the potential for a mutation that can lead to resistance, and antibiotics that have an effect on DNA have been shown with in vitro experiments to potentially contribute to this predisposition to resistance.¹¹⁷

The data regarding the role of antibiotics in causing DNA damage that leads to increased resistance via hypermutation

become relevant when one considers potential mechanisms for the increasing toxin production in *C. difficile* that has led to such problems as toxic megacolon, bowel perforation, and death. In an attempt to better understand outbreaks of clinical disease caused by toxin-producing strains of *C. difficile*, the genetics of epidemic strains were studied.^{118,119} In these studies, an 18-base-pair deletion in the *tcdC* gene, which normally downregulates production of toxins A and B, was noted. An additional finding was the presence of binary toxin genes. These factors were thought to contribute to the hyperproduction of toxin expressed in clinical outbreaks. The epidemiologic analysis of these outbreaks identified fluoroquinolone therapy as a risk factor in recent *C. difficile* outbreaks.¹¹⁸⁻¹²⁰ These observations challenge the critical care clinician to again consider the potential of unintended antibiotic consequences in the selection of empiric antibiotic therapy in seriously ill patients.

In addition to *C. difficile*, the effect of antibiotics on toxin production has been studied in gram-positive organisms. In a study investigating the effects that cell wall-active antibiotics and protein synthesis inhibitors have on transcription and translation of genes for PVL, AH, and TSST-1, Miller and associates demonstrated that subinhibitory concentrations of nafcillin induced and prolonged messenger RNA (mRNA) expression for PVL, AH, and TSST-1.⁸⁶ A clinical interpretation of these data suggested by the investigators is that inadvertent use of β -lactam antibiotics to treat MRSA infections may contribute to worse outcomes.

Even though such processes as DNA damage leading to hypermutation and increases in virulence factors are important considerations in discussions about unintended consequences, the most mature knowledge base related to the collateral damage of antibiotics is the risk of these agents to contribute to the expression of bacterial resistance.

CLINICIAN RESPONSES TO MULTIDRUG RESISTANCE

In the studies addressing increased mortality rates associated with inadequate initial antimicrobial therapy for serious infections,^{2,7} unanticipated bacterial resistance was a frequent reason for not initially selecting a drug to which the organism was susceptible. An important insight is provided in the study by Trouillet and colleagues, who evaluated the risk factors for resistance in patients with VAP.¹²¹ The conclusions of that study were that use of antibiotics within the past 15 days and mechanical ventilation of at least 7 days' duration were the most important factors. When these two parameters were used in subcategories to evaluate the predisposition for selecting resistant organisms, antibiotic use was a more influential factor than was mechanical ventilation. This fact highlights the dual role that antibiotics play in the ICU: (1) treatment of infection and (2) potential selection of the resistant organisms that lead to the next episode of infection. The challenge for the clinician is to achieve the appropriate degree of balance between these two opposing effects.

Integral to effective antibiotic stewardship in the ICU is an understanding of those factors that lead to the expression of antibiotic resistance. A basic understanding of the mechanisms of resistance and the organisms that express

them can lead to more effective empiric therapy and a more efficient de-escalation process.

MECHANISMS OF ACTION AND OF RESISTANCE

On the most fundamental level, an antibiotic must bind to a target site before the pharmacologic property that kills the organism can be invoked. As examples, β -lactams bind to PBPs to prevent synthesis of the bacterial cell wall, and fluoroquinolones bind to DNA gyrase to prevent replication of the genetic elements required for bacterial replication. For an antibiotic to reach its target site, there must be penetration through the outermost part of the bacterial cell wall. Impermeability of those sites precludes the drug from getting to its target site. Once an antibiotic enters the outermost portion of the bacterial cell wall but before it binds to its target site, there are two potential mechanisms by which the drug can be precluded from having its effect: one is enzymatic destruction of the antibiotic; the other is extrusion of the drug from the bacteria via pumps referred to as efflux pumps. Because of the importance of enzymatic destruction and of efflux that leads to the drug resistance encountered in the critical care setting, these two mechanisms of action will be discussed in some detail. However, it is important to consider the importance of target-site binding and of impaired penetration because both of these mechanisms of resistance have practical implications for the clinician.

BINDING TO A TARGET SITE

Although there are multiple sites to which antibiotics might bind and thereby exert their mechanism of action, the one that is probably the most relevant in clinical practice is the binding of β -lactam antibiotics to PBPs. PBPs are best considered as enzymes on the innermost part of the bacterial cell wall that play a role in the synthesis of that structure. When bacteria have alteration in their PBPs such that antibiotics can no longer bind to that site, then those organisms have a mechanism by which they demonstrate resistance to that antibiotic. In clinical medicine, the two most important examples of resistance mediated via altered PBPs are methicillin resistance in *S. aureus* and penicillin resistance in *S. pneumoniae*. The significance of this for the clinician is probably best represented by a relatively common practice. Assume that a patient has an infection presumed to be caused by *S. pneumoniae* that is unresponsive to penicillin. An uninformed practice pattern is the addition of a β -lactamase inhibitor like clavulanic acid to a drug like amoxicillin as the next agent used in an attempt to treat that infection. Because the resistance in penicillin-resistant *S. pneumoniae* is not via β -lactamase production but rather via altered PBPs, the β -lactamase inhibitor adds nothing to the regimen. In contrast, a higher dose of penicillin might overcome the problem of decreased binding of the antibiotic to the PBPs, with the resultant effect of improved efficacy.

PENETRATION THROUGH THE BACTERIAL CELL WALL

For an antibiotic to reach its target binding site, it must penetrate the bacterial cell wall. One route that can be used by certain antibiotics is through trimers of proteins referred to as porins, which are located in the bacterial cell wall.

Originally intended as a point of access for nutrients into the bacteria and excretory products out of the bacteria, porin channels have been used as the route of entry for certain antibiotics, most notably, the carbapenems. When an organism becomes deficient in these porins, then carbapenems are not able to enter the bacteria, which ultimately leads to a lack of binding to PBPs and resultant clinical resistance. The most important example of resistance mediated by porin channel closure is the resistance of *P. aeruginosa* to carbapenems. For the clinician in the ICU, it is important to know that *P. aeruginosa* possesses three mechanisms of resistance regulated by genetic operons on the chromosome: (1) AmpC β -lactamases; (2) efflux pumps; and (3) outer membrane porin alterations.^{122,123} Because the clinician will not have information at the time of empiric therapy regarding which, if any, of these mechanisms might be in play in the *P. aeruginosa* being targeted, regimens for infections like hospital-acquired pneumonia often target more than one of these mechanisms of pseudomonal resistance.¹⁰

ENZYMATIC DEGRADATION

Enzymatic degradation of antibiotics is one of the most widespread and variable mechanisms of antibiotic resistance available to microorganisms. Furthermore, although resistance in gram-negative bacilli may occur by any of the aforementioned mechanisms, one that provides a foundation for understanding the interaction between antibiotic use and antibiotic resistance is β -lactamase. These enzymes have the ability to cleave, and thereby render ineffective, the four-membered β -lactam ring that is common to all the β -lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems, and monobactams) as well as the β -lactamase inhibitors (i.e., clavulanic acid, sulbactam, and tazobactam). Because researchers have identified countless β -lactamase enzymes, clinicians must employ a clinically relevant classification system to categorize them into practical groups. The most widely used classification system of β -lactamase enzymes places them into four distinct functional classes (i.e., Ambler classes A, B, C, and D). This system can be further simplified to consider three types of β -lactamases with relevance to clinical medicine: (1) AmpC β -lactamase (which is a class C β -lactamase also referred to as a type 1 enzyme), (2) extended-spectrum β -lactamases (ESBLs), and (3) carbapenemases.

Type 1 β -lactamase

Type 1 β -lactamases (AmpCs) are chromosomally mediated, with the product of the *ampC* gene (hence the term AmpC β -lactamases) being the archetype. See Table 51.1 for organisms commonly felt to produce type 1 β -lactamase, their substrate, and antibiotics felt to be stable in the presence of the enzyme. According to data from the Centers for Disease Control and Prevention's National Nosocomial Infections Surveillance (NNIS) system, these organisms account for 10% to 33% of nosocomial infections involving blood, surgical site, urine, and lung.¹²⁴ Even though these pathogens do not always produce type 1 enzymes, this potential does exist and must be taken into consideration if initial antibiotic therapy is to be appropriate. Because type 1 β -lactamases have an affinity for cephalosporins (and have therefore been referred to by some authors as cephalosporinases),

Table 51.1 Characteristics of Type 1 β -Lactamase-Expressing Organisms

Common β -Lactamase-Expressing Organisms*	Susceptible Substrate	Stable Antibiotics
<i>Serratia</i>	Penicillins	Aminoglycosides
<i>P. aeruginosa</i>	β -Lactamase inhibitors	Carbapenems
Indole-positive <i>Proteus</i>	First-, second-, and third-generation cephalosporins	Fluoroquinolones
<i>Citrobacter</i>		Fourth-generation cephalosporins†
<i>Enterobacter</i>		
	Monobactam	

*"SPICE" (or "SPACE") Bugs: If *Acinetobacter* is substituted for indole-positive *Proteus*, then the mnemonic SPACE applies.

†Not as predictably stable as the other three classes.

third-generation cephalosporins are not predictably stable in the presence of type 1 enzymes.¹²⁵ Also lacking stability are the β -lactamase inhibitors, of which tazobactam is the most likely to resist destruction by these enzymes.

Exposure to specific antibiotics may influence a microorganism's ability to produce type 1 β -lactamases. In a classic paper from the infectious diseases literature, two mechanisms have been described by which this occurs: (1) induction and (2) the selection of spontaneous mutant strains (previously referred to as stable de-repression).¹²⁶ Sanders and Sanders¹²⁶ explored the property of induction when they performed an investigation in which they incubated an organism with the potential to produce type 1 β -lactamases overnight in the presence of antibiotic. After this incubation, they performed an assay for type 1 β -lactamase. If they subsequently detected the enzyme, they described the process as induction. Strong inducing antibiotics identified in this report were cefoxitin, imipenem, and clavulanic acid. Of note, upon removal of the inducing antibiotic, the β -lactamase production ceased before the next dose of drug was due to be given. The investigators thus described induction as a reversible in vitro phenomenon.¹²⁶

In the years since the description of induction as an in vitro phenomenon, no definitive evidence has been accumulated demonstrating that induction in gram-negative organisms leads to clinically significant resistance in patients; however, the *ampC* gene product can lead to alarming resistance patterns through another mechanism.

What has been proved to occur in patients is the selection of spontaneous mutant strains of bacteria.¹²⁶ As stated earlier, organisms that possess the *ampC* gene typically possess complex regulatory mechanisms that prevent overexpression of the gene; however, a certain number of bacteria within clinical isolates (often in the 10^{-6} to 10^{-7} range) will have spontaneous mutation(s) that allows them to overproduce type 1 β -lactamase.¹²⁶ When certain broad-spectrum antibiotics are given, the sensitive nonmutated organisms are killed; however, the genetic mutant strains proliferate and become the predominant organisms. Once this occurs, the clinical isolate will now exhibit resistance to a broad

range of β -lactam antibiotics. Most notable of the antibiotics that have been described in the literature to select these “stably de-repressed” mutants are the third-generation cephalosporins.^{127,128}

A clinically relevant lesson can be learned from the story of how type 1 β -lactamases lead to the expression of resistance. In the overwhelming majority of instances with gram-negative organisms, antibiotics do not cause induction of resistance, but rather certain antibiotics efficiently kill susceptible organisms while leaving resistant mutants to proliferate, thereby selecting the resistant microbes to flourish. This process of selection, not induction, is the basis for most of the resistance that is encountered in the clinical setting; thus, when clinicians suspect infection with organisms capable of producing type 1 β -lactamase, they should avoid certain antibiotics (i.e., antibiotics that provide good substrate for the product enzyme) that efficiently select these mutants.

Extended-Spectrum β -Lactamases

An increasingly common problem facing clinicians and clinical microbiologists is the presence of ESBLs, which are broad-spectrum β -lactamase enzymes produced by such pathogens as *Klebsiella*, *Escherichia coli*, *Enterobacter*, and *Proteus*. First described in the 1980s, these enzymes may occur on the basis of a change of only one amino acid in the β -lactamases normally produced by these pathogens.¹²⁹ Despite the minimal structural change, the enzymes have the capacity to inactivate many broad-spectrum β -lactam drugs. Of note, use of any of several classes of antibiotics, notably third-generation cephalosporins and fluoroquinolones, has been identified as a risk factor for selecting ESBLs.^{130,131}

The resistance that occurs in such ESBL producers is of importance for the clinician in initial antibiotic selection in two regards. First, with β -lactam antibiotic therapy, even antibiotics that generally are stable in the presence of β -lactamases may not have predictable activity. Inferior outcomes associated with extended-spectrum cephalosporins such as cefepime and with β -lactam/ β -lactamase inhibitor combinations, such as piperacillin-tazobactam, have been described;¹³² one proposed mechanism is inoculum effect, with diminished susceptibility as the size of the inoculum is increased from 10^5 to 10^7 organisms.^{132,133} An alternative explanation for the lack of activity by certain β -lactam antibiotics has been proposed by Craig and Bhavnani.¹³⁴ As the number of bacterial colony-forming units (CFUs) increases from 5×10^5 to 5×10^7 , approximately 100 times more β -lactamase is released from bacteria lysed after antibiotic exposure. Variations in antibiotic efficacy may rest on the increased release of enzyme in infections with larger inoculums of organisms (e.g., pneumonia and intra-abdominal abscess). Thus, in vitro susceptibility may not predict in vivo outcome for treatment of infectious diseases.

Unlike the type 1 β -lactamase, the ESBL is not chromosomal; rather, it is carried on a large plasmid, which may contain genetic material encoding the machinery that conveys resistance to many classes of antibiotics. For example, the resistance genes for aminoglycosides may be located on the same plasmid as those encoding an ESBL. As a result, gentamicin and tobramycin resistance often occurs in ESBL producers.¹³³ With fluoroquinolones, multiple

mechanisms may contribute to quinolone resistance in ESBL producers. Topoisomerase mutations (i.e., target modification) may be associated with decreased binding. The *qnr* gene codes for a protein that wraps around DNA gyrase, thereby preventing quinolones from attaching to target binding sites.^{135,136} In addition, ESBL-producing organisms may possess efflux pumps, and because fluoroquinolones are subject to extrusion from bacteria by means of these pumps, efflux is a potential mechanism of quinolone resistance in ESBL producers.¹³⁷

During the early years of infection with ESBL-producing organisms, infections occurred almost exclusively in either hospitalized patients or in those who had been exposed to antibiotics. In the early 2000s, ESBL infections that occurred in the community setting in patients who had never been hospitalized and who had not been previously exposed to antibiotic were reported.¹³⁸ Risk factors for ESBL infections included rates in the 35% range of infections caused by ESBL-producing organisms in patients who had no previous health care contact.¹³⁹ With the awareness of community ESBL infections came the identification of large increases within relatively short periods of time of specific types of ESBLs (e.g., the enzyme CTX-M, which refers to a cefotaximase that was initially identified in Munich, Germany) occurring predominately in urinary tract isolates of *E. coli* in community settings.¹⁴⁰ Perhaps the best explanation for why infection with ESBL-producing pathogens might originate in the community setting in patients without the risk factors for either selective antibiotic pressure or person-to-person spread of the organism was suggested in the review by Jacoby and Munoz-Price.¹³³ Genes for CTX-M-type enzymes are found on the chromosome of *Kluyvera*, a genus of rarely pathogenic commensal organisms found in the gastrointestinal tract. The postulation was that pathogenic organisms such as *E. coli* producing CTX-M-type enzymes appear to have emerged by plasmid acquisition of β -lactamase genes from commensal organisms with which they have close proximity in an environmental reservoir (e.g., the gastrointestinal tract). It is awareness of such a trend for community-acquired resistant pathogens that may influence the initial empiric therapy of patients with either a gastrointestinal or urinary tract source of infection who present ill enough to require ICU admission.

Although infection with ESBL-producing organisms has been associated with significant clinical consequences, no definitive recommendations exist for how to optimally treat such infections, and no antibiotic presently on the market has an FDA-approved indication for treating infections caused by ESBL-producing pathogens. In the absence of such data but with the important ramifications of such infections, recommendations must be extracted from the medical literature. The reviews by Jacoby and Munoz-Price¹³³ and by Paterson and Bonomo¹²⁹ have listed carbapenems as a drug of choice for infections caused by ESBL-producing pathogens. Influencing this recommendation are the facts that (1) ESBL-producing pathogens are often resistant to fluoroquinolones and aminoglycosides because resistance mechanisms for these classes of antibiotics are often carried on the same large plasmid containing the genetic elements for ESBL production and (2) carbapenems (although β -lactam agents) are paradoxically stable in the presence of ESBLs.

It is important for the clinician to consider whether one carbapenem might be more favorable than another for the treatment of infections caused by ESBL-producing organisms. In the era of antimicrobial stewardship, a principle of importance in such considerations is whether the collateral damage of antibiotics that may result in selecting resistant strains of *P. aeruginosa* can be prevented. Although not a universally accepted tenet, the concept of pseudomonal sparing is of potential importance. The clinical approach to carbapenems that is useful in such a consideration is to divide this class of antibiotics into those agents with activity against *P. aeruginosa* (i.e., imipenem, meropenem, doripenem) versus the carbapenems without significant activity against *P. aeruginosa* (i.e., ertapenem). Incorporating the data from Sanders and Sanders,¹²⁶ selection of strains of resistant *P. aeruginosa* occurs when a spontaneous mutant with the genetics for drug resistance is allowed to grow because sensitive nonmutant strains of the organism have been killed by antibiotic therapy. Although numerous references regarding antibiotic selective pressure leading to drug-resistant *P. aeruginosa* have been published, two publications are representative of how a process might be favored by pseudomonal-active antibiotics.

In a 2-year case-control study of 2613 patients admitted to three ICUs in a large teaching hospital in Paris, France, prolonged receipt of antibiotics with specific antipseudomonal activity, most notably ciprofloxacin, was associated with the emergence of multidrug-resistant *P. aeruginosa*.¹⁴¹ The authors concluded that if treatment with an antibiotic active against gram-negative bacteria is needed, agents with little antipseudomonal activity should be preferred over those with specific antipseudomonal activity to limit the emergence of multidrug-resistant *P. aeruginosa*. Using data from 779 isolates of carbapenem-resistant *P. aeruginosa*, Carmeli and colleagues showed by univariate analysis that the risk factors for isolation of carbapenem-resistant *P. aeruginosa* were the administration of group 2 carbapenems (imipenem, meropenem) ($P < 0.0001$), aminoglycosides ($P = 0.034$), or penicillins ($P = 0.05$).¹⁴² The group 1 carbapenem ertapenem was not associated with imipenem-resistant *P. aeruginosa* ($P = 0.2$).

Since the introduction of ertapenem onto the market, there have been theoretical concerns that use of this non-pseudomonal carbapenem might select for strains of carbapenem-resistant *P. aeruginosa*. Ecology studies conducted over the first 9 years that ertapenem was on the market specifically addressed this concern, and those studies have been published in a review article on the topic.¹⁴³ Results from the 10 clinical studies evaluating the effect of ertapenem use on the susceptibility of *Pseudomonas* to carbapenems uniformly showed that ertapenem use did not result in decreased *Pseudomonas* susceptibility to the antipseudomonal carbapenems.

With the increasing prevalence of ESBL infections, including those in the community setting that might be severe enough to require ICU admission, an unanswered question is whether noncarbapenem therapy might be appropriate for some patients. This question was addressed in a post-hoc analysis from Spain of patients from six published prospective cohorts who had bloodstream infections due to ESBL-producing strains of *E. coli*.¹⁴⁴ Most of these patients had the urinary tract as the site of

origin of the bloodstream infection. These results suggested that amoxicillin/clavulanic acid and piperacillin/tazobactam might be suitable alternatives to carbapenems for treating patients with bloodstream infections due to ESBL-producing *E. coli* if the isolate was susceptible in vitro to these agents. Unanswered by the review is the optimal management of ESBL-producing *E. coli* bloodstream infections originating outside the urinary tract and of infections caused by pathogens other than *E. coli* that produce ESBLs.

Of the mechanisms of resistance encountered in clinical practice, the story of ESBLs is illustrative of two insightful philosophical points in antibiotics prescribing. First, the community pattern of ESBL resistance in patients without classic risk factors for any form of bacterial resistance challenges the clinician to consider such a mechanism in any patient who presents with severe infection of the gastrointestinal or genitourinary tract. Such clinical situations highlight the importance of stratification of antibiotic therapy based on severity of illness, especially given the data about inappropriate antibiotics as a risk factor for increased mortality rate in serious infections. Second, the increasingly faced dilemma of broad patterns of resistance in *P. aeruginosa* in an era with a paucity of new antibiotic drug development challenges the clinician to judiciously use antibiotics in an attempt to preserve the antibiotics presently available. The concept of pseudomonal-sparing is therefore reasonable to incorporate when possible into antibiotic selection.

Carbapenemases

Carbapenemase is the name used for those β -lactamases that have the ability to inactivate carbapenems, which at the present time is the broadest class of antimicrobial agents available to the ICU physician. To understand carbapenemases in a clinically applicable manner requires a fundamental set of facts. The numerous types of β -lactamases that exist today can be subdivided based on the foundation of their chemical structure: those that have a serine base; and those that have a metallobase. Within that subdivision, one can then approach the four Ambler classes of β -lactamases: classes A, B, C, and D. Class B β -lactamases have a metallobase, and the initial carbapenemases described clinically were class B metalloenzymes. An example from clinical practice of a class B metalloenzyme is the New Delhi metallo- β -lactamase (NDM) found in certain Enterobacteriaceae. After the identification of metallo- β -lactamases, microbiologists began identifying serine-based β -lactamases that were in Ambler group A (which is the same class in which the majority of ESBLs are found). These enzymes were produced by *K. pneumoniae* and were subsequently referred to as KPCs (*K. pneumoniae* carbapenemases). Although there are also class D serine-based carbapenemases such as the OXA-type enzymes produced by organisms like *Acinetobacter* species, the class A and class B carbapenemases are the ones that are most important today in clinical practice.

The name *carbapenemase* has the potential to be misleading. In an insightful discussion of carbapenemases written at the time when these enzymes were just beginning to be commonly recognized as causes of clinical infections, it was acknowledged that KPC carbapenemases in actuality hydrolyze β -lactams of all classes, with the

most efficient hydrolysis observed for nitrocefin, cephalothin, cephaloridine, benzylpenicillin, ampicillin, and piperacillin.¹⁴⁵ That review went on to state that the carbapenems imipenem and meropenem, as well as the β -lactam antibiotics cefotaxime and aztreonam, were hydrolyzed with one tenth the efficiency of the penicillins and early cephalosporins. The microbiologically important message was that the KPC family of carbapenemases has a broad hydrolysis spectrum that includes most β -lactam antibiotics. It is with such a basic science foundation that one can begin to approach the role of antibiotics in selecting organisms that produce carbapenemases.

There has been an inclination by some clinicians to assume based on the name *carbapenemase* that carbapenem antibiotics are the most likely to select such a pattern of resistance. Although a definitive answer for such a question cannot be found from prospective clinical trials, multiple reports in the literature support the conclusion that several classes of antibiotics have been linked to subsequent infection with carbapenemase-producing bacteria. As a basic piece of information, one can assume that patients become colonized with such resistant pathogens and that any broad-spectrum antibiotic has the ability to kill the normal flora and thereby allow the resistant strains to grow and to cause clinical disease. In the absence of identifying a specific class of antibiotics responsible for selecting carbapenemase-producing bacteria, there has been a focus in the medical literature to identify other variables that contribute to the problem. Two representative papers provide an important insight related to the association between prior antimicrobial therapy and the subsequent identification of carbapenemase-producing bacteria. In a 4-year case-control study ($n = 102$), the only covariate independently associated with carbapenem-resistant Enterobacteriaceae in all multivariate analyses was the cumulative number of prior antibiotic exposures.¹⁴⁶ A 26-month double case-control study ($n = 96$ ESBL-CRKP and 55 ESBL-CSKP) from Greece identified both prior cumulative exposure to antibiotics and increasing duration of prior treatment as risk factors.¹⁴⁷ Shown in this study to be associated with the isolation of carbapenemases was therapy with β -lactam/ β -lactamase inhibitor or with the combination of fluoroquinolone and carbapenem. These data are consistent with previous reports that no particular class of antibiotic is the predominant predisposing factor for selection of carbapenemase production. Knowledge of this information by the ICU physician is important because it (1) debunks the myth that carbapenemases are selected only by one class of antibiotics (and, therefore, that restriction of only one class of antibiotics can manage such a problem) and (2) supports the intensity and duration of antibiotic therapy as the most important variables in creating the milieu in which carbapenemase-producing bacteria are selected.

Therapy for infections caused by carbapenemase-producing bacteria has been extremely challenging, and at the present time there are neither definitive nor predictable recommendations that guarantee clinical success. In the absence of such data, the clinician is challenged to make clinically relevant deductions from the published literature. The findings from 15 studies and reports in treating

infections caused by KPCs showed success rates of 75% with aminoglycosides, 73% with polymyxin combinations, 71% with tigecycline, 40% with carbapenems, and 14% with polymyxin monotherapy.¹⁴⁸ At the time of writing of this chapter, the antimicrobial agents accepted as having the most potential activity based on in vitro susceptibility are tigecycline, polymyxins, and aztreonam.¹⁴⁹ There are evolving data suggesting a potential role for carbapenems as a therapeutic option if (1) the MIC of the infecting organism is 4 mg/L or less and (2) the carbapenem is given in combination with another active agent.¹⁵⁰

The examples of carbapenem resistance (whether on the basis of carbapenemase or other mechanism of resistance) in *Pseudomonas*, *Acinetobacter*, *Stenotrophomonas*, and *Klebsiella* underscore an important concept in antimicrobial therapy for the critical care clinician, for whom such patterns of resistance are becoming increasingly prevalent in the ICU. When multidrug resistance occurs, it cannot be predictably assumed that such resistance is on the basis of exposure to the broadest class of antibiotic to which the organism is resistant. To accept such a flawed assessment could result in limited use of that class of antibiotic, which could then shift to increased use of the actual class of antibiotic that led to the pattern of resistance. The other clinically relevant observation in many of the recently described outbreaks is that inadequate infection control contributed to the spread of resistant strains that had been selected by antibiotics.^{132,151,152}

EFFLUX PUMPS

Efflux pumps are three-component systems, contained within the bacterial cell wall, that allow bacteria to eliminate antibiotics that have entered. Initially described in 1980 as a mechanism of resistance in tetracyclines, efflux was recognized in 1988 as a contributor to fluoroquinolone resistance.¹⁵³ In recent years, the contribution of efflux to clinical resistance has broadened, with important implications for treatment of serious infections. The composition of this system has been nicely detailed.^{154,155} The pump itself (also referred to as the transporter) lies in the cytoplasmic membrane and is designated MexB, MexD, or MexF. It is attached via a linker lipoprotein (MexA, MexC, or MexE) in the periplasm to the third component, the exit portal (OprM, OprJ, or OprN), which lies in the outer membrane. These three components of the efflux pump normally are under repressor gene control and therefore are not clinically active.

P. aeruginosa has several efflux systems, with MexAB-OprM and MexEF-OprN having particular clinical significance: The MexAB-OprM system contributes to both intrinsic and acquired resistance; and the MexEF-OprN system contributes only to acquired resistance.¹⁵⁶ The MexAB-OprM system is expressed constitutively in cells grown in standard laboratory media, where it contributes to intrinsic resistance to a number of antimicrobials, including fluoroquinolones, tetracyclines, piperacillin, cefepime, aztreonam, and certain carbapenems.¹²³ Of the β -lactams, only carbapenems appear to be poor substrates for MexAB-OprM; however, different carbapenems vary with regard to their susceptibility to efflux. Meropenem and doripenem are subject to efflux, and expression of the MexAB-OprM efflux system has been correlated with resistance to meropenem.¹⁵⁷ By contrast,

imipenem is not subject to efflux.¹⁵⁶ It has been suggested that this may be due to the need for efflux systems with MexAB-OprM to access their substrates within the cytoplasmic membrane. Meropenem is much more amphiphilic than imipenem, which may explain why imipenem does not act as a substrate for MexAB-OprM whereas meropenem does.¹⁵⁷ Such a microbiologic property may explain why a gram-negative isolate may be susceptible to imipenem but resistant to meropenem.

The ability of fluoroquinolones to select certain *nfxC* (*mexT*) mutants has been discussed.^{122,154} In addition to resistance to fluoroquinolones, these mutants may have decreased susceptibility and even clinical resistance to carbapenems (e.g., imipenem, meropenem) that occurs on the basis of either closure of porin channels in the outer membrane of the bacterial cell wall (with resultant impermeability) or upregulation of an efflux pump (which allows the bacteria to eliminate drug that has penetrated the organism's cell wall). Such newly recognized information may help explain patterns of increasing carbapenem resistance in health care institutions in which carbapenem use has not recently increased.

THE CLINICAL RELEVANCE FOR UNDERSTANDING ANTIBIOTIC RESISTANCE

An understanding of this concept takes on significance with the increasingly common problem in ICUs of the development of resistance to multiple antibiotics. Referred to as multidrug-resistant organisms, these pathogens may be the cause of clinical failure of antibiotic treatment if an inappropriate therapeutic regimen is used. A common mistake in clinical practice is to assume that the major predisposition to a pattern of resistance is the overuse of the broadest category of antibiotic to which a pathogen is resistant. Several examples are important in the understanding of this concept.

A classic example of multidrug resistance in gram-negative organisms is the resistance in *P. aeruginosa*. As previously noted, multiple resistance mechanisms regulated by genetic operons on the chromosomes of *P. aeruginosa* have been described, including efflux pumps, AmpC β -lactamases, and outer membrane porin closure.^{122,158} For infections such as HAP and VAP, in which *P. aeruginosa* is a pathogen targeted with empiric therapy and for which fluoroquinolones are offered as an option in the initial regimen,^{10,15,159} data on the risk of fluoroquinolones leading to multidrug resistance via efflux mechanisms become especially noteworthy. Additionally, because of the ability of certain organisms such as *P. aeruginosa* to express multiple mechanisms of resistance, many experts recommend avoiding the use of traditional antipseudomonal agents (i.e., a pseudomonal-sparing regimen) when treating infections in which *Pseudomonas* is not a suspected pathogen, as the use of overuse these agents may result in the development of multidrug resistance in *Pseudomonas* isolates.¹⁴¹

The experience with carbapenem-resistant *A. baumannii* in Brooklyn, New York, provides an important insight into the problem of selection of resistance by one class of antibiotic to an entirely different class. In a study to evaluate the endemicity of *A. baumannii*, all unique patient isolates of this pathogen were collected from 15

Brooklyn hospitals over a 3-month period.¹⁵² Antibiotic susceptibilities, ribotyping, and the relationship between antibiotic use and resistance rates were determined. Among the 224 carbapenem-resistant strains of *A. baumannii*, ribotyping demonstrated that one strain accounted for two thirds of the isolates and was present in all of the 15 participating hospitals. The strongest predisposition to selection for this pathogen was cephalosporin use. Known *A. baumannii* resistance mechanisms include chromosomally associated β -lactamases and porin protein mutations,¹⁶⁰ so it can be assumed that this represents selection of carbapenem-resistant mutant strains by the cephalosporins.

A retrospective analysis of critically ill trauma patients with late-onset gram-negative pneumonia showed that the antibiotic most associated with pneumonia due to *Stenotrophomonas maltophilia* was cefepime.¹⁶¹ These data on cephalosporins as a risk factor for *S. maltophilia* infection are similar to those in an earlier report that identified use of ceftazidime and imipenem as associated with similar rates of *S. maltophilia* acquisition in hospitalized patients.¹⁶² The suggestion by these reports is that broad-spectrum agents, more so than one specific agent, may kill sensitive bacteria and allow pathogens such as *Stenotrophomonas* to become clinically expressed.

DE-ESCALATION

The concept of de-escalation therapy incorporates the dual goals of (1) initially attempting to decrease mortality rate by selecting the appropriate antibiotic for empiric therapy but (2) decreasing the time that a patient is exposed to the broad-spectrum therapy that might be necessary to get initial therapy administered correctly.

DECREASING BROADNESS OR NUMBER OF AGENTS

Classically, there have been three ways that de-escalation can occur. The most intuitively understood is changing from a broad-spectrum agent to a narrower spectrum agent based on culture and sensitivity data. As is well known to those who practice in the intensive care setting, culture data are often negative in the sickest patients, and the option of de-escalating based on culture data is often not available. The de-escalating process becomes less clear when diagnostic studies do not yield an obvious pathogen. Perhaps an appropriate manner of employing the information gained by a negative culture is to allow the nonrecovery of certain organisms to influence the alteration of an existing regimen. HAP, including VAP, provides a clinically applicable example of this concept. In an attempt to minimize mortality rates, patients with HAP typically receive as empiric therapy a three-drug regimen that includes coverage against MRSA and *P. aeruginosa*. Guidelines of the ATS/IDSA for HAP have suggested that clinically improving patients not on antibiotics when cultures are obtained may have therapy against MRSA and *P. aeruginosa* stopped if sputum cultures are negative for these pathogens.¹⁰

A third technique for de-escalating is to shorten the duration of therapy.

DURATION OF THERAPY

Because antibiotics may be a risk factor for resistance,¹²¹ it is important in the process of antibiotic stewardship to identify opportunities to minimize exposure to these therapeutic agents. One possibility is by decreasing the duration of therapy to the shortest duration necessary to achieve an optimal clinical outcome.¹⁶³ Often the decisions regarding traditional durations of therapy find their basis not in controlled trials or prospective studies, but rather in expert opinion. Although certain infections, such as *S. aureus* bacteremia, require well-defined and often prolonged durations of intravenous therapy,^{164,165} trials in VAP have challenged some of the classic tenets and have resulted in recommendations for shorter durations of therapy when compared to the traditional regimens.

Dennesen and coworkers¹⁶⁶ evaluated the response to antimicrobial therapy administered according to ATS guidelines in 27 patients diagnosed with VAP in a study that initially used a bronchoalveolar lavage (BAL) along with clinical parameters to confirm the diagnosis of VAP but subsequently used semiquantitative tracheal aspirates for microbiologic surveillance. All patients in this study received appropriate antibiotic therapy. After initiation of antibiotic therapy, T_{\max} (maximal temperature over a 24-hour period), $\text{PaO}_2/\text{FiO}_2$ (ratio used to quantify impairment of oxygen gas exchange in the lung), white blood cell count, and semiquantitative cultures of endotracheal aspirate were monitored. Resolution of clinical parameters occurred primarily within the first 6 days of therapy. Using cultures of endotracheal aspirates, the investigators found that colonization with *P. aeruginosa* persisted throughout the duration of treatment, whereas colonization with *S. aureus*, *H. influenzae*, and *S. pneumoniae* resolved shortly after initiation of therapy. Acquired colonization, predominantly with resistant pathogens such as *P. aeruginosa* or members of Enterobacteriaceae, usually occurred in week 2 and frequently preceded a recurrent episode of lung infection. On the basis of these data, it was suggested that 7 days may be an appropriate duration of therapy for patients with VAP.

Ibrahim and colleagues¹⁶⁷ evaluated a clinical guideline for the treatment of VAP using 7 days of therapy. A total of 102 patients were prospectively evaluated, 50 before institution of the guidelines and 52 after institution. In addition to more frequent choice of adequate initial antibiotic treatment after implementation of the clinical guideline, patients also had shorter antibiotic courses when treated under the guideline. No mortality rate difference was noted between the two groups. As was the case with the study by Dennesen and coworkers,¹⁶⁶ a second episode of VAP was more likely to occur in the patients receiving the longer, traditional duration of therapy.

Chastre and associates¹⁶⁸ conducted a prospective, multicenter, randomized, double-blind study of 401 patients with VAP confirmed by quantitative cultures obtained by bronchoscopic protected specimen brush (PSB) or BAL, or both. Only patients who had received initial appropriate antibiotic therapy were included. Therapy was divided into two categories: short course, which was given for 8 days in 197 patients, versus long course, which was given for 15 days in 204 patients. Clinical efficacy was similar between the short-course and long-course groups. Because slightly more

patients with nonfermenting gram-negative bacilli (e.g., *P. aeruginosa* and *A. baumannii*) assigned to the 8-day regimen had pulmonary infection recurrences, the investigators were unable to demonstrate the noninferiority of the 8-day regimen for infection by such pathogens compared with the 15-day course of therapy. Multiresistant pathogens more frequently caused recurrences in patients who received the 15-day regimen. Even though the findings from this study do not definitively prove that therapy for HAP or VAP can be limited to 7 days, they lend support to the findings by Dennesen¹⁶⁶ and Ibrahim¹⁶⁷ and their colleagues.

MINIMIZING CLINICAL RESISTANCE

In the absence of a significant pipeline of antibiotics for treating multidrug-resistant organisms, it is important for the clinician to use antibiotics judiciously so that currently available agents are active for as long as possible. Several approaches toward achieving this goal have been described.

For many years, the standard approach to antibiotic prescribing occurred in a homogeneous manner in which a single antibiotic or limited numbers of antibiotics were used as the “workhorse” agents in empiric therapy.¹⁶⁹ Such an approach to antibiotic prescribing often was associated with restricted formularies, the thought being that limiting broad-spectrum agents might prevent the emergence of resistance. Unfortunately, this approach did not take into consideration the possibility that the inadequate therapy in seriously ill patients might not be reversible when the initial antibiotics were changed to the correct agents once susceptibilities were known. In addition, it was during this era of restricted formularies that the proliferation of bacterial resistance began to occur. Because an inherent risk with homogeneous antibiotic use is the selective pressure that when applied can lead to resistance, other approaches must be considered.

Heterogeneous antibiotic use, in which antibiotic selection is based not on hospital mandates but rather on issues related both to the patient and the pathogens involved in the infectious process, may decrease selective pressure.¹⁶⁹ Heterogeneity can be achieved in any of several ways. A strategy by which multiple or all classes of antibiotics are available for use (i.e., antibiotic heterogeneity) has been suggested as part of a broader effort aimed at curtailing antibiotic resistance within ICUs. As a potential alternative to cycling, a mathematical model was developed to compare antibiotic cycling with *mixing*, in which antibiotic variation is random as opposed to the regulation that occurs with a process like antibiotic cycling.¹⁷⁰ The premise for such a comparison is that mixing imposes greater fluctuation in selective conditions, thereby yielding greater heterogeneity than occurs with cycling. In this study, the results were underlaid by a simple ecologic explanation that led to the conclusion that cycling is unlikely to be effective and may even hinder resistance control and that mixing may yield more favorable results in terms of preserving antibiotic susceptibility.

In contrast with homogeneous antibiotic use, which was developed to control resistance, heterogeneous use is aimed at managing resistance.¹⁶⁹ Because resistance at some level

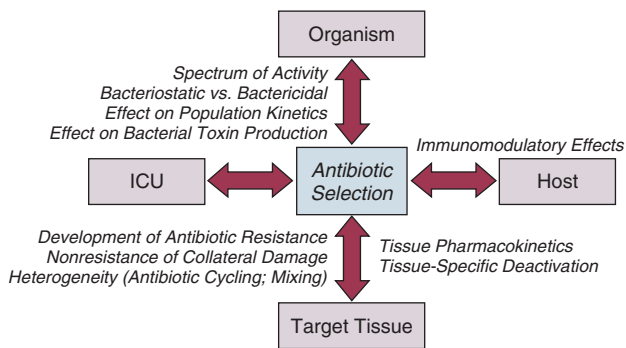

Figure 51.3 The interplay of antibiotic selection with principles relevant to host, organism, intensive care unit, and target tissue. Adequate antibiotic therapy is dictated by more than matching spectrum of antibiotic activity with a pathogen's *in vitro* susceptibility.

is an inevitable part of medical practice, the latter approach seems more insightful.

CONCLUSIONS

At a time when bacterial resistance is becoming more prevalent but during which antibiotic development is relatively stagnant, the critical care clinician is faced with the somewhat daunting challenge of achieving clinical efficacy without compromising the antibiotic armamentarium that exists at present. For this to be accomplished, the interplay of several important concepts will drive the decision process. As depicted in [Figure 51.3](#), these considerations include the organism, the host, and the targeted tissue, as well as specific issues related to the ICU itself.

Armed with the knowledge of these variables, health care providers now have the foundation for achieving the first goal of antibiotic stewardship—education. Nevertheless, in the recently developed guideline for antibiotic stewardship, it was acknowledged that education alone, without incorporation of active intervention, is only marginally effective in changing antimicrobial prescribing practices and has not demonstrated a sustained effect. An understanding of the principles governing antimicrobial selection in the ICU should better position critical care clinicians for practicing the art of antibiotic prescribing in a manner that both achieves efficacy for optimal outcome and preserves the integrity of the antibiotics available for this task.

KEY POINTS

- Initial appropriate antibiotic therapy (defined as matching antibiotic to pathogen susceptibility), with early dose administration, reduces mortality rate in the treatment of serious infections.
- Adequate antibiotic therapy extends beyond appropriate therapy and includes dose optimization, ensuring target tissue penetration, and consideration of combination therapy.
- Empiric and directed antibiotic regimens for the individual patient also are influenced by factors that the critical care physician must recognize: time- versus concentration-dependent killing; synergy versus

KEY POINTS (Continued)

antagonism; immunomodulatory antibiotic properties; inhibition of bacterial protein synthesis; and organ-specific deactivation.

- In selecting antibiotics for serious infections, the clinician should consider not only the individual therapeutic efficacy but also the potential for unintended antibiotic consequences, such as selection of resistant microorganisms.
- Because antibiotic therapy is a risk factor for selecting resistant microorganisms, antibiotics should not be broader in coverage, or given longer, than necessary. Initial broad and aggressive antibiotic therapy should, therefore, be rapidly de-escalated as soon as is clinically possible.
- It is important to recognize that resistance to a class of antibiotics may be selected by therapy with an entirely different class of drugs.
- With the increasing prevalence of community-acquired mechanisms of resistance such as ESBL production, it is important to stratify initial therapeutic options based on severity of illness.
- Knowledge of the mechanisms by which antibiotic-resistant bacteria are selected may lead to more judicious patterns of antibiotic use that may help to manage the evolving patterns of resistance that are occurring globally.
